For some unknown reason mankind in general holds to the belief that good health is an inalienable right; that no matter what else goes awry, it should continue. Comparatively little care, therefore, is taken of this most precious gift, yet if anything goes wrong we feel aggrieved. Inasmuch as there is no way by which our health can be guaranteed permanently, we are making an attempt to protect ourselves against our own neglect by health insurance.

Unfortunately the ability to insure is in inverse ratio to the necessity. In other words, the man who is drawing the largest salary is the one best able to carry insurance, yet it is he who can live in the best surroundings and for that reason be the least likely to become ill. The man who needs the insurance is the one whose environment is poor, because his wage is insufficient to procure anything better.

For many years little attention was paid to the public health, but it is now evident that there is no question of greater importance. The prosperity of a community depends primarily upon the good health of its individual members. If conditions are such that twenty-five out of every thousand employees in American industries are constantly incapacitated by illness, it is time that something more be done. It is the physician who has done much in the past to promote preventive measures, but he seems predestined and foreordained to continue his efforts, even if he eventually destroys his means of livelihood.

It is evident that there must be some provision by means of which any worker, no matter how poorly paid, may receive proper medical attention. It is not only a matter of importance to the man and his family, but the entire social economy is affected, and for that reason all the various elements must eventually take a hand. The employers, the employees, and the public are all concerned, and such being the case each will have to do his share. As it is now, the public, through its State and municipal governments, pays large sums for the poor and the permanently incapacitated. Again the principle of prevention can be invoked; it would be better to provide proper relief at the first indication and thus lessen the chance of future illness. The fact remains, however, that health insurance for the great mass of workers will be provided sooner or later, and also that an additional burden will fall upon the medical profession. In order that this burden be not unduly heavy, it is necessary for the physicians to interest themselves in the laws that will be enacted, not to oppose, but to see that they are fair to all concerned so far as the medical aspects are involved, and democratic rather than bureaucratic in type. Class legislation which seeks to impose compulsory insurance upon wageworkers as differentiated from salaried workers, is essentially un-American. There is a world of difference between general insurance against ill health and compulsory health insurance.

APOPLEXY AND DIET.

The saying that a man is as old as his arteries is generally attributed to Sir James Paget, although this has been disputed. While there may be doubt as to who first gave to the world the phrase, its truth cannot be denied. Perhaps the most critical time of life with respect to the risk of an apoplectic seizure is that lying between fifty and sixty-five years of age; the person who has lived not wisely but too well, one who has indulged too freely in the pleasures of the table, is most susceptible to an attack of this nature. It is the lethargic, full blooded, thick and short necked subject who eats and drinks more than is good for him and who does not take suffi-

cient exercise, who most frequently falls a victim to this class of disorder. F. Barlow, writing on the subject in the *Medical Press* for July 12, 1916, notes that the majority of seizures occur on Sunday or Monday, owing probably to the greater indulgence in the joys of the table on the day of rest and the slight increase in excitement consequent on the return to business. It may likewise be remarked that total abstinence from alcohol confers no immunity on its votaries if they are big eaters and cocoa drinkers. Indeed, the fact is more obvious in cases of apoplexy, that sufferers dig their graves with their teeth, than in any other disease. Alcohol is frequently made the scapegoat for an attack of this character, when really excessive eating is to blame. Heredity appears to play a part of some importance in predisposing to an apoplectic stroke, and a person whose family history suggests a liability in this direction should pay particular attention to his mode of life, especially when he reaches the age of fifty years, which Barlow terms, "entering the danger zone."

From all points of view treatment should be of a preventive nature, before an attack and not after, and upon this axiom great stress should be laid. Patients with degenerated arteries should be made to realize the vital importance of leading a careful life if they wish to attain old age. Moderation in all things should be their motto, and they should avoid excitement. Naturally, diet becomes a factor of inestimable moment. Meals should be light and of an easily digestible character, and meat should be cut out of the menu or its use greatly restricted. Barlow recommends that once a week twenty-four hours should be kept as a fast so far as solid food is concerned. Attention must be paid to the regular action of the bowels, but, as a rule, it is inadvisable to employ strong purgatives; it is best, if possible, to secure regular action by means of suitable food, exercise, etc. The use of petroleum oil is indicated in many cases.

The point which should be chiefly emphasized is that apoplexy is generally brought about by an injudicious manner of living, of which excessive eating of unsuitable food is the main cause, and that it may be prevented from progressing to an acute attack, even when the arteries are more or less seriously degenerated, by adopting a rational mode of life. To cite another adage, we should eat to live and not live to eat.

REPORTING INDUSTRIAL DISEASES.

There seems to be little doubt that after the cessation of the great war there will be instituted another—a struggle for industrial supremacy. It is highly desirable, of course, that the United States should not neglect any means by which her own position in that struggle may be strengthened, and preservation of the health of the industrial workers thus becomes a vital problem. Here it is necessary for the physicians of a community and its legislators to work in harmony. Laws should be enacted upon the advice of experienced health officers requiring that diseases which are in the nature of chronic intoxications from substances handled in various occupations should be reported, not with the idea of debarring those affected from their means of livelihood, but in order that the exact nature and extent of the diseases may become known. Physicians should cooperate willingly in carrying out these regulations; then in time would accumulate a wealth of statistical material bearing on these occupational diseases which would probably be of great service in the campaign to eradicate them.

Some steps in the right direction have already been taken. Rhode Island, in 1915, passed a law making compulsory the reporting by physicians of poisoning from lead, phosphorus, arsenic, brass, wood alcohol, etc. The sanitary regulations of New York's department of health require the same reporting and also demand that cases of apparent poisoning from articles of food be reported. Alabama forbids the employment of children wherever the work is such that poisonous products are evolved. Pennsylvania improves on this in that she adds that children must not work in any establishment wherein their morals may be jeopardized.

In the course of time it may be that we shall have a complete system of reporting these diseases among the workmen, so that by the time we are actively engaged in the battle for the world's business the private soldiers in our industrial army will be as nearly as possible physically fit.

THE BLOOD IN DIAGNOSIS AND TREATMENT.

While the gross appearance of the blood, as extravagantly withdrawn in the days of indiscriminate phlebotomy, was superficially noted, it is but recently that the study of that fluid has been found of any help in diagnosis. Within a quarter of a century, however, the study of the blood has come to be almost of routine importance, and its examination is rapidly undergoing greater and greater elaboration.

The color of the blood was perhaps the first diagnostic sign discovered, and an exact determination of the hemoglobin content followed the invention of test cards and other hemoglobinometers. Then came the counting of cells, the staining of corpuscles, and the differential count; finally, the bacterial examination which has proved of much value, the testing of its bacterial properties, the discovery of

the Widal and the Wassermann tests, the properties of cytolysis, and the knowledge, essential for blood transfusion, of the great individual differences in the blood.

More recently the field of chemistry of the blood has been opened up, and the possibilities seem very great. We have had the tests, qualitative and quantitative, for urea, for uric acid, for creatinin, for sugar, for total nitrogen, for carbon dioxide. Already our public laboratories are advertising to do, while you wait, "complete blood tests," as they formerly announced their readiness to do complete analyses of the urine. What comes forth from this chemical study of the pathological blood will be something to have in prospect. We can only hope that in cases of faulty metabolism it may be of aid, not only in early diagnosis, but in the prevention of many distressing diseases.

In the way of treatment, the transfusion of blood has been long tried, and the recent perfecting of technic makes it a more promising therapeutic procedure for the future. The intravenous injection of drugs is safer and more useful. The inoculation of blood from immune subjects for the prevention or cure of infectious disease is, theoretically, most alluring, but is by no means established as therapeutically valuable.

PELLAGRA AND THE VITAMINES.

It is becoming more and more borne in upon the minds of those who have studied pellagra, both from the experimental and clinical standpoints, that it is a deficiency disease and as such may be placed in the same category as beriberi, scurvy, and rickets. The researches of Dr. Casimir Funk and others have thrown much light upon the question of the relationship of the vitamines to deficiency diseases, and it really seems as if we were on the high road not only to the solving of the problem of the causation of what may be termed with sufficient accuracy deficiency diseases, but of a partial solution of the problem of the origin of many other diseases and disorders. It is now universally allowed that diet plays a predominant part in the causation and development of numerous maladies and consequently in their prevention and treatment. Moreover, the painstaking researches of Funk and a band of earnest investigators seem to show that the absence or lack of vitamines in a diet is mainly responsible for a large number of conditions of ill health.

So far as pellagra is concerned, Surgeon Joseph Goldberger, of the Public Health Service, and his associates appear to have proved clinically, or it has been proved by following their suggestions, that pellagra is due chiefly to vitamine absence or insufficiency. Goldberger and his fellow workers concluded: "Pellagra is not a communicable disease, neither infectious nor contagious, but is essentially of dietary origin. It is dependent on some as yet undetermined fault in a diet in which the leguminous protein component is disproportionately small and the nonleguminous vegetable component disproportionately large; and no pellagra develops in those who consume a mixed, well balanced, and varied diet, such, for example, as that furnished by the Government to the enlisted men of the Army, Navy, and Marine."

Doctor Voegtlin, as an outcome of his experience in the south, is strongly inclined to attribute the pellagra which is more or less frequent in certain parts of the southern States to the lack of vitamines in the food eaten by the inhabitants. It occurs among those who subsist mainly on corn products, upon bread made from highly milled corn flour, corn from which the husk or pericarp has been completely removed by the milling. The husk contains the vitamine element. It has been demonstrated to the satisfaction of many authorities that beriberi is caused by eating highly polished rice, rice from which the pericarp containing the vitamines has been removed. The analogy then between pellagra and beriberi is close, and it might not be anticipating too much to state that pellagra, like beriberi, is a deficiency disease and caused chiefly by the vitamine element of the food being destroyed. The discovery that the lack of vitamines is the most potent cause of deficiency diseases is valuable, for the means of preservation and cure are obvious and at hand.

DOGS.

Dr. Joseph S. Bolton, of Nottingham, England, writes to the *British Medical Journal* for July 22d, hoping that a recent editorial note in that periodical will be followed up by the readers and lead to some effectual action. Every one will agree, he thinks, that the number of dogs in town streets is far in excess of requirement. Doctors who visit the poor are well aware that dogs are kept by persons who have no proper accommodations for them, and even by those who are too poor to provide wholesome food for their children. Doctor Bolton advises a guinea tax on dogs, which would reduce their number by one half, much to the satisfaction of motorists and all drivers of vehicles, the safety and comfort of cyclists, and the gratification of sanitarians and all who care for the cleanliness of the streets.

HEALTH INSURANCE AND THE A. M. A.

At the last meeting of the American Medical Association, says *Public Health Reports* for July 21, 1916, the house of delegates recommended that every constituent State association be requested to establish a committee on social insurance to work in conjunction with the committee of the American Medical Association. The American Academy of Medicine adopted a resolution authorizing a committee to be known as the "social insurance committee," to make careful study of the problem of social insurance, especially those phases known as health insurance, industrial insurance, accident insurance, mothers' insurance, and insurance against nonemployment, and to submit to the executive committee before December 1, 1916, a preliminary report dealing with health insurance and its relation to physicians.

The American Association of Industrial Physicians and Surgeons, organized in Detroit June 12, 1916, created a committee to study health insurance in its relation to the industrial physicians. The conference of State and Territorial health authorities with the United States Public Health Service has a standing committee on health insurance. The report of this committee, which was made in May, 1916, appears, *loco citato*, page 1919. The committee is still at work on this subject.

DANGEROUS GOLF BALLS.

We have referred editorially to the danger of cutting into certain makes of golf ball, and we note that L. V. Cargill, F. C. S. (*Practitioner*, July, 1916), in a paper on Recent Work in Ophthalmology, thinks it wise to mention the matter. As the writer remarks, it cannot be too widely known that great risk attends the practice. The contents of the core are generally of a strongly alkaline, soapy consistence, and may contain zinc or calcium chloride or barium sulphate, and being enclosed in a machine wound rubber ribbon under great pressure, the contents escape when the ball is punctured, with sufficient force to strike the ceiling of a room ten feet high. Cases of irremediable damage to vision have occurred both in America and Great Britain, and onlookers as well as players have apparently been victims.

News Items

Personal.—Dr. Donald B. Armstrong has resigned as director of the Department of Social Welfare of the New York Association for Improving the Condition of the Poor, to become assistant secretary and director of the community tuberculosis experiment of the National Association for the Study and Prevention of Tuberculosis.

Mount Sinai Hospital, New York, has announced the receipt of a gift of $150,000 to endow its department of abdominal surgery. The donor is Charles A. Wimpfheimer, who had previously given $230,000 to the institution.

Mercy Hospital, Chicago, has recently opened a new four story addition at a cost of $300,000. The first floor of the structure is reserved for children, a large playroom being one of the features. The second and third floors are divided into wards and private rooms, and the fourth floor is to be devoted to obstetrical service.

Rockefeller Foundation Gifts.—The recent report of the Rockefeller Foundation states that between January 7 and August 7, 1916, the total sum appropriated by the foundation was $3,369,667. Between June 28th and July 31st the appropriations were $506,289, the largest being $189,985.47, to the China Medical Board. On June 28th the foundation appropriated $80,000 to the Rockefeller Institute for Medical Research for its current expenses and $80,000 for laboratory and the hospital alterations. On July 11th $15,000 was given to the Red Cross for work in Serbia and $50,000 to the International Young Men's Christian Association for recreation centres for soldiers on the Mexican border. On July 14th the foundation gave $50,000 to the New York Health Department for the infantile paralysis fight, beside $7,000 for the expenses of the American Social Hygiene Association. It also gave $25,000 to aid Belgian children in Switzerland. Since the first of the year the gifts from that part of the foundation's fund devoted to objects selected by John D. Rockefeller personally have amounted to $575,775.

Additional Poliomyelitis Clinics.—The special poliomyelitis lecture clinics conducted recently under the auspices of the Department of Health were so successful that numerous requests have been received asking that they be repeated. Through the kind cooperation of attending physicians of the various hospitals now treating these cases, a new course of clinics has been arranged as shown in the schedule below. It is to be noted that attendance at these clinics will be strictly limited. Physicians desiring to attend should apply in advance to the respective hospitals for cards of admission. Groups will be formed in the order of application. When the group is complete the applicant will be referred to the clinic held on the following week: Bellevue Hospital—Pavilion 32 (contagious), every Monday at 4 p. m. Lebanon Hospital—every Tuesday at 3:30 p. m. Willard Parker Hospital—every Wednesday at 4 p. m. Babies Hospital—every Thursday at 4 p. m. Mt. Sinai Hospital—every Friday at 4 p. m. Kingston Avenue Hospital—every Friday at 4 p. m. The clinics will continue for the next five or six weeks. There will be no clinic at Bellevue Hospital on Labor Day, September 4th. We advise our readers to register at once.

Examination for Naval Medical Corps.—The next examination for appointment in the Medical Corps of the Navy will be held on or about October 23, 1916, at Washington, D. C.; Boston, Mass.; New York, N. Y.; Philadelphia, Pa.; Norfolk, Va.; Charleston, S. C.; Great Lakes (Chicago), Ill.; Mare Island, Cal.; and Puget Sound, Wash. Applicants must be citizens of the United States and must submit satisfactory evidence of preliminary education and medical education. The first stage of the examination is for appointment as assistant surgeon in the Medical Reserve Corps, and embraces the following subjects: (a) Anatomy, (b) physiology, (c) materia medica and therapeutics, (d) general medicine, (e) general surgery, (f) obstetrics. The successful candidate will attend the course of instruction at the Naval Medical School. During this course he receives a salary of $2,000 per annum, with allowances for quarters, heat, and light, and at the end of the course, if he successfully passes an examination in the subjects taught in the school, he is commissioned an assistant surgeon in the navy to fill a vacancy. Full information with regard to the physical and professional examinations, with instructions how to submit formal application, may be obtained by addressing the Surgeon General of the Navy, Navy Department, Washington, D. C.

The Medical Society of the Missouri Valley.—The annual meeting of the Medical Society of the Missouri Valley, under the presidency of Dr. John P. Lord, will be held in Omaha, Thursday and Friday, September 21st and 22d, at the Hotel Fontenelle. The arrangements are being made by a committee under the auspices of the Omaha-Douglas County Medical Society. The program will be limited to twenty papers, thus affording more time for discussion. A cordial invitation is extended to physicians of other States.

American Aid for Belgian Physicians.—Dr. F. F. Simpson, of Pittsburgh, treasurer of the Committee of American Physicians for the Aid of the Belgian Profession, reports for the month of July, 1916, the following contributions: Dr. Miles F. Porter, of Fort Wayne, Ind. (second contribution), $5. Receipts for the month of July, $5. Receipts previously reported, $7,941.86. Total receipts, $7,946.86. Previously reported disbursements: 1,625 standard boxes of food at $2.20, $3,575; 1,274 standard boxes of food at $2.30, $2,930.20; 353 standard boxes of food at $2.28, $804.84. Total disbursements, $7,310.04. Balance, $636.82.

Infantile Paralysis and the State.—Dr. Hermann M. Biggs, State Commissioner of Health, has announced that one of the most important methods in the control of infantile paralysis is to keep children from infected districts separate from others and under constant observation so that they might promptly receive proper treatment if any signs of the disease developed. In order that this might be more generally understood, a circular letter has been prepared by the State Department of Health and sent to the proprietors of all hotels and lodging houses, calling their attention to Regulation 5 of the Sanitary Code, which requires the proprietors of hotels, boarding houses, and lodging houses, and all other persons to report to the local health officer all facts relating to a person presumably affected with a communicable disease, and Regulation 4 of the Special Departmental Regulations for the control of infantile paralysis, which requires hotel proprietors, boarding house keepers, and all other persons to report the name and address of all children under the age of fifteen years arriving at their hotel, boarding house, or household. By this method Doctor Biggs hopes to have the health officers fully apprised of all children arriving in their districts who had come from centres where cases of infantile paralysis existed.

Proposed Supervisory Commission of American Red Cross Not Approved by British Government.—Great Britain has declined to approve an offer of the American Red Cross to send to the Central Powers of Europe a commission of satisfactory persons to receive American Red Cross shipments, superintend their distribution to hospitals, and supervise their use. Such a proposal was made by former President Taft, chairman of the Central Committee of the American Red Cross, on June 10th. In his reply, which is dated July 12th, Sir Edward Grey, Secretary of State for Foreign Affairs of Great Britain, calls attention to the following statement published in the *New York Times* for May 12th, which sets forth the views of the British government on the assertions of the American Red Cross:

His Majesty's Government have no reason to believe that there is an absolute lack in the territory of the Central Powers of the materials required for Red Cross supplies; they have, on the contrary every reason to suppose the reverse for, to give only one instance, not long ago a medical member of the Austrian general staff, Professor Hochenegg, stated publicly that there was no shortage and no prospect of shortage in medicines or bandages, nor even in highly special medical remedies, so that Austria was hardly concerned in the success of the protest made by the American Red Cross against the obstacles placed by the Allies in the way of the export of such articles from America. In these circumstances it is evident that if any deficiency in these supplies exist, as to which there appears to be no evidence, it must be due to the fact that the Central Powers prefer to use the materials for other purposes, and any steps that may be taken to give them further supplies would conduce, not to the increased welfare of the sick and wounded, but merely to set free larger quantities of such materials for belligerent purposes.

Free Advice on Tuberculosis.—Free expert advice for consumptives and others interested in tuberculosis is given in a pamphlet just issued by the National Association for the Study and Prevention of Tuberculosis, entitled What You Should Know About Tuberculosis. The pamphlet was prepared by a committee of experts of international prominence consisting of Dr. Charles L. Minor, of Asheville; Dr. David R. Lyman, of Wallingford, Conn.; Dr. H. R. M. Landis, of Philadelphia; Dr. John H. Lowman, of Cleveland, and William H. Baldwin, of Washington. It contains the latest and most authoritative information about tuberculosis. It deals with the nature of the disease; how infection may take place; how the disease is cured; how the family may be protected; what the patient may do after discharge, and how the disease may be prevented in the community. A copy of the pamphlet will be sent free to anyone applying for it at the office of the Committee on the Prevention of Tuberculosis, State Charities Aid Association, 105 East Twenty-second Street, New York, and large supplies of copies for local distribution may be had at cost from the committee.

Chemists and Technical Men to Meet in New York.—Official announcement of the meeting of the American Chemical Society, to be held in New York, September 25th to 30th, in conjunction with the Second National Exposition of Chemical Industries, will be issued to the members by Dr. Charles L. Parsons, secretary, on August 15th. Dr. Charles H. Herty, of the University of North Carolina, president of the American Chemical Society, will open the exposition on Monday, September 25th, at 2 o'clock in the afternoon, with an address reviewing the history of chemistry and the chemical industries in this country and outlining developments since the outbreak of war in Europe. The presidents of cooperating societies, such as the American Electrochemical Society, the American Institute of Mining Engineers, and the American Paper and Pulp Association will follow Doctor Herty with speeches of welcome and reviewing the progress made in the industries represented by them.

The first general session of the American Chemical Society will open at Columbia University on Tuesday morning, September 26th, and arrangements are being perfected for a public meeting in the large hall of the College of the City of New York on Tuesday afternoon when addresses will be made of general public interest pertaining to the interesting developments in the field of applied chemistry during recent years.

The program of the week's meetings will provide for general conferences on subjects in which the chemists of the country are now interested and it is intended that the lecture hall of the Grand Central Palace and Rumford Hall in the Chemists' Club building will be occupied each afternoon at the same time by one or other of the different divisions of the society for the discussion of such industrial topics as the production of dyestuffs, medicinal chemicals, industrial alcohol, the manufacture of paper pulp and byproducts, oils and motor fuels, glassware and porcelain, steel alloy metals, new developments in chemical industries, etc.

On Wednesday and Thursday mornings a general symposium on colloids will be held, theoretical considerations being discussed on the first day and the industrial applications of colloid chemistry on the second day.

The American Electrochemical Society has planned a series of interesting meetings. The electrochemical group will open its meeting later in the week, on Thursday, September 28th, with a technical session devoted to a review of American progress in the electrochemical industry. A complimentary smoker will be held on Thursday evening and on Friday evening there will be a joint banquet at the Waldorf-Astoria of the members of the American Chemical Society, the American Electrochemical Society, and the Technical Association of the pulp and paper industry. This will be a subscription banquet and the price of tickets to members will be $3.50; additional tickets for guests will be obtainable at cost, or about $7.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirty-first Communication.

DIPHTHERIA.

It would indeed be fortunate if we could develop as specific and distinct means to combat all diseases as we have for diphtheria. Instead of administering a drug which in one case goads a function to increased activity, or in another case depresses a function, we simply add to the blood stream agencies naturally developed by the system to counteract diphtheria toxin and repress bacterial development. We truly aid nature by furnishing quickly to the system antitoxins which the body is not always able to provide in amounts adequate to meet the emergency, and this natural antidote must be forthcoming, else the system will be promptly overwhelmed by the highly poisonous products of bacterial catabolism. Such a logical means of treatment is obtained by injecting the serum of horses highly immunized to diphtheria toxins. In this serum there is a high percentage of agencies antagonistic to poisons of the Bacillus diphtheriæ, wherever found, so that administration of this antitoxin to a person ill with the dread disease is not unlike sending in a heavy brigade to support a sorely pressed battalion.

This aid is not always sufficiently prompt, however; and there result more or less severe disturbances of body functions to be combated temporarily by medicines with definite predictable reactions. Here we arrive on controversial ground. For instance, one recent popular text (Anders) says: "Alcohol . . . is the most powerful drug in our possession to offset the ravages of the disease on the nervous centres, and for the control of the circulation." Yet from the viewpoint of advanced pharmacology it is difficult to see how alcohol can be anything but harmful in the treatment of diphtheria, except as it might possibly conserve the processes of oxidation. It is of course not impossible that alcohol may differ materially in its action in the presence of diphtheria toxins from the way it acts on well subjects in the pharmacological laboratory, but there is no convincing evidence to support such a contention. The pharmacodynamics of alcohol indicates that in its action on the nervous system and circulation it would be synergistic to the diphtheria toxin rather than antagonistic; they are both depressant on the heart and the great nervous centres. All of our laboratory experimentation indicates that alcohol is not a drug to be employed internally in the treatment of diphtheria.

Strychnine may be used advantageously, not for any assumed stimulant action on the heart, but because it serves to maintain the sensory irritability of the cord and, to a less extent, of the medulla.

Caffeine is the most nearly trustworthy stimulant of heart action, but is to be used chiefly when the beat is thin and weak; when arrhythmia exists, digitalis will usually restore the normal periodicity; when the heart is fluttering, combinations of caffeine and minute doses of atropine may prove valuable. Frequently caffeine is best administered in warm saline (160° F.) solution given slowly as an enema; the action of the drug is prompt on both heart and kidney, while the additional water volume received by the blood aids in the elimination of toxic material.

No one drug is relied upon for local effect; but from some experimental data it seems that some of the essential oils, like oil of eucalyptus in solution, might prove somewhat inhibitory of bacterial activity. Theoretically, the vapors of iodine in steam would be helpful. Frequent cleansings of the nose and throat with douches or sprays are desirable.

Treatment of Operative Acidosis.—A. C. Burnham (*American Medicine,* June, 1916) gives as the routine treatment: 1. Adequate nutrition by mouth, especially in the form of carbohydrates; 2, forced carbohydrate feeding in the form of glúcose solutions by mouth—a teaspoonful of glucose to a glass of water. It may also be given by rectum, or subcutaneously, an ounce to a quart; 3, bicarbonate of sodium solutions given by mouth, rectum or subcutaneously; 4, saline solutions by hypodermoclysis during the operation, and, 5, morphine for the relief of pain and to prevent the evil effects of excessive external stimuli.

Treatment of Acidosis in Pregnancy.—Herbert Williamson (*American Medicine,* June, 1916) says that chloroform should never be administered because the existing lesions are made worse and the acidosis is increased. Calomel should not be given because the lesions in the liver and kidney produced by mercurial poisoning are the same in nature as those of pregnancy toxemia. For a similar reason mercurial douches should not be given. Where acidosis exists intravenous infusion with sodium bicarbonate or sodium acetate solution should be employed. Glucose should be administered so that the fat metabolism may be spared. If acidosis exists in a pregnant woman suffering from chronic nephritis, the uterine cavity should be emptied at once.

Treatment of Retained Material in Abortions.—J. Soler Julia (*Revista de Ciencias Medicas de Barcelona,* May, 1916) after a careful review of the literature and of 169 cases treated by curettement in the Santa Cruz Hospital in Barcelona, decides that the proper routine is curettement in all women who show either hemorrhage or retention of material after miscarriage, and furthermore that it is of the greatest importance to maintain uterine drainage by means of tubes. Hysterectomy can be accepted only in cases of uterine gangrene without generalized infection, and such cases are rare. If there is collapse with generalized lesions of the liver or kidneys, all treatment is futile.

The Drug Habit.—Frank A. McGuire and Perry Lichtenstein (*Medical Record,* July 29, 1916), from a study of 12,000 cases in the city prison, conclude that the treatment of such cases cannot be carried out except in a hospital or sanatorium, and that the gradual reduction method, so called, as practised by physicians outside of hospitals is to be condemned as useless. They find that beyond the craving for the drug there are no physical symptoms on withdrawal of opium or cocaine, but that such symptoms are usually noticed in morphine and heroine addicts. Their experience shows that few patients trace their addiction to a physician's prescription, but nearly all place the blame on friends.

Asepsis and Antisepsis in War Surgery.—U. Giannettasio (*Riforma medica,* July 3, 1916) from extensive observation in active service at the front, is convinced that hypochlorous acid is the most potent antiseptic known today, as in four or five days it cleans up the most gravely septic wounds. Its deodorizing powers are well known and thus it is useful in dysidrosis and bromidrosis of the axillæ and feet, in superficial gangrene, as well as in putrid cavities. It is stated that some of the projectiles contain an amalgam of phosphorus which produces necrosis when allowed to remain in the body tissues and here again the use of hypochlorous acid would tend to oxidize this phosphorus and render it harmless.

Constipation in Military Practice and Its Treatment.—A. Martinet (*Presse médicale,* June 15, 1916) calls attention to the remarkable prevalence of constipation recently observed among soldiers in active service, due in part to insufficiency of green vegetables and fruit in the diet, a relatively sedentary life in the trenches, and intestinal inhibition of psychic origin. In the matter of diet the simplest prophylactic measures would consist in the addition of prunes, raisins, and "pounded" apples and pears, together with the avoidance of white bread. From the remedial standpoint, the physician himself may prescribe lin or psyllium seeds, and in particular agar agar, together with the ingestion of pure water on awaking or retiring. Exercises specially designed to excite intestinal activity are entirely appropriate. Morning and evening each of the following movements should be slowly carried out four to twelve times: 1. Elevation of the extended lower extremities from dorsal decubitus to a vertical position; 2, approximation of the thighs to the trunk, with flexion at the knees; 3, raising the trunk to sitting posture from the floor, with arms extended forward; 4, elevation of the abdomen from the floor by extension of the spinal column; 5, throwing the trunk forward along the floor from a kneeling position, and return. Where the measures already given prove insufficient, drugs may be used. These include liquid petrolatum, especially useful where there is hyperchlorhydria and a spasmodically contracted intestine (a frequent condition among troops)—one to four teaspoonfuls on awaking or one hour before supper; belladonna in the form of pills each containing 0.01 gram of the extract and of the powdered leaves is also useful—one to three pills a day, supplemented if necessary by a spoonful of castor oil or by magnesia in the evening; or, castor oil may be used as an initial laxative, followed by liquid petrolatum, daily or at longer intervals, with or without belladonna. In the numerous cases with distinct hepatic congestion small daily amounts, four to six grams, of sodium sulphate in a pint of water, to be taken in two doses, on awaking and later in the morning, are of value. For a frank purgative, derivative effect in congestive states, gastroenterogenous intoxication, hypertension, threatened uremia, etc., sodium sulphate in hypertonic solution is appropriate, e. g., twenty-five to sixty grams of the salt in 200 to 250 c. c. of water, with or without sugar. During active campaigning the following pills may with advantage be ordered for occasional use:

℞ Extracti hyoscyami, ...0.02 gram;
Extracti rhei, ...
Extracti rhamni purshianæ, ...āā 0.05 gram;
Extracti euonymi, ...
Saponis, ...q. s.
Fiat pilula No. 1. Sig. Two to three pills a day at meal time.

Yeasts, Probably Pathogenic, in Throat Cultures.—Grover (*Journal of Infectious Diseases,* July, 1916) noticed yeastlike organisms in many routine examinations of throat cultures sent in on account of suspected diphtheria. Thinking that they might be of importance pathologically ninety cultures were studied. From these, seventeen distinct varieties of yeast were isolated. These were all inoculated subcutaneously into guineapigs with the result that thirteen of the varieties used caused glandular enlargement. Another series of guineapigs was inoculated by scarifying the mucous membrane of the mouth and rubbing in some of the culture. In eleven of these there developed within forty-eight hours a dirty yellowish false membrane. Grover concludes that certain of the yeasts are factors in the production of throat infections, either alone or in association with diphtheria.

Some Uses and Abuses of Massage.—E. Bellis Clayton (*Lancet,* July 8, 1916) finds that one of the commonest of the abuses is the long continued administration of massage in a case of functional paralysis. Instead of helping the victim the massage usually makes his condition worse. In functional paraplegias there is often some rigidity of the back and the legs, but it is useless to rely on massage for a cure. The patient must be got up on his feet almost forcibly and taught to stand and walk, but he can be greatly encouraged by the judicious use of massage and faradism for the first week or two. Paralyzed muscles are best treated by massage and galvanism with passive movements of the joints. Massage also finds a decided field of usefulness in the treatment of flabby heart and poor circulation, for which it should be combined with mild breathing exercises. It is particularly applicable in patients confined to bed. For the great majority of joint injuries massage and passive movement is an essential form of treatment. Massage should always be instituted as early as possible and pursued systematically if any good is to come from its employment..

The Treatment of Amebic Dysentery.—John Pelham Bates (*Jour. A. M. A.*, July 29, 1916) finds that ipecac or emetine has excellent results, but treatment of dysentery is often incomplete, as shown by a considerable tendency to relapse after the withdrawal of emetine. Recurrence should not take place if all the organisms have been destroyed, and this should be possible in the majority of cases. The most satisfactory treatment is as follows: The first requisite is absolute rest in bed until the subsidence of all acute symptoms. An initial purge with castor oil or a saline should be given. Then a daily dose of half a grain of emetine is administered for four days, when the dose is increased to one grain daily and continued until not less than five or six grains have been given. The emetine is then discontinued and bismuth subnitrate is substituted. The bismuth promotes the healing of the ulcers and acts also as an amebicide, destroying such parasites as may have been left by the emetine. The dose should be one dram every four hours while the patient is awake, continued until the stools have become well formed. Then the dose may be reduced to a dram thrice daily until the patient is discharged as well. As soon as the effects of the initial purge have passed, an enema of two to three quarts of normal saline solution should be given every four hours and continued as long as the emetine is being given. After that the enemas may be reduced to three and finally to one a day. During the acute symptoms the only food should be from four to eight ounces of sweet milk every two hours. Later the quantity may be increased and the interval between feedings lengthened. Soft boiled or poached eggs and a slice of dry toast may also be given. With improvement the diet may be slowly increased until the normal is reached. This treatment requires four to eight weeks. The greatest resistance to treatment will be found in cases where the ulcers extend well up into the ileum.

Colloid Gold as an Adjuvant in the Treatment of Typhoid Conditions.—Barachon (*Paris médical*, June 17, 1916) reports excellent results from the use of colloid gold in the form of collobiase, an electrochemically made preparation. Intramuscular injections gave very inconstant results, most marked in mild cases and during defervescence, but entirely insufficient in grave cases. Intravenously, the remedy was generally given in ascending doses ranging from 0.1 to two c. c. None of the patients received even the cold pack as a substitute for cold baths—the latter being impracticable under present circumstances. Each injection was observed to cause typically, at the expiration of fifteen minutes, a severe chill, followed by a rise in temperature to as high as 42° C., sometimes accompanied by slight transient delirium and a general sensation of heat. This was soon followed by a copious sweat, and the latter, in turn, by marked general improvement. The preexisting headache disappeared, the mucous membranes often regaining their normal moisture, the mind was clarified, prostration passed off, and the patient felt improved and sank into a quiet sleep. The temperature fell as much as 40° C., and temporarily remained low. The general condition was, however, especially benefited. When the temperature is not sufficiently lowered or the improvement less than expected, Barachon gives a second injection on the next day; if results are good, the injections are repeated only at two day intervals. The rare cases in which there is no improvement are those of profound and long standing infection, and such lack of effect is of unfavorable prognostic significance. Like all colloid solutions, colloid gold has bactericidal and antitoxinic properties. The constitutional effects seem, however, to show that it acts especially by exciting the defensive processes of the organism. The drug is said to cause a sudden doubling in the number of polynuclear neutrophiles in the blood and thus an intense phagocytosis, the latter favored by a corresponding and equally rapid rise in the opsonic index. The sweat produced does not take place at the expense of the urinary output, an increase in the renal elimination of water being nearly always observed. Each injection is followed, as it were, by a period of truce with the disease, all toxic symptoms disappearing, and although the course of the disease is, perhaps, not shortened by the treatment, the latter enables the patient to pass through the ordeal under unusually favorable conditions. Though useful even at the height of the disease, the injections should, if possible, be begun at the outset, while the defensive resources of the body are still unimpaired. They should be repeated as often as fever and particularly the general condition seem to require them. They are contraindicated only in threatened perforation or hemorrhage and in myocarditis. In cases of sudden defervescence and profuse sweating in weak subjects the heart should, for the sake of caution, be temporarily sustained with one or two injections of camphorated oil.

Tuberculins and Vaccines.—E. Hayling Coleman (*Brit. Med. Jour.*, July 8, 1916) considers that in the use of vaccines there are four classes of cases. The first is that in which vaccine treatment is usually successful and is more likely to give results than any other form of treatment. This group includes cases of recurring boils and carbuncles, chronic nasal and postnasal catarrh due to the pneumococcus, chronic bronchitis of old persons, colon bacillus cystitis and many cases of chronic gleet. The second group contains cases in which the usual remedies have failed and vaccines are known to have succeeded. In this group are cases of acne, nasal catarrh not due to the pneumococcus, obstinate catarrhal asthma, whooping cough, and tracheal infections. The third class includes cases of serious disease in which a vaccine can do no harm and may increase the chances of recovery, such as pneumonia and general septic infections. Finally there is the group in which vaccines often fail and other remedies almost always do, including rheumatoid arthritis, chronic otitis media, colitis, some skin diseases and septic anemias. In almost every type of condition in which a vaccine is to be used much better results will be secured from the employment of an autogenous vaccine than from a stock vaccine. Further, where there is a mixed infection, the two or more offending organisms should be used in separate vaccines, so that the dose of each may be varied according to the benefit produced.

Simple Technic for Intravenous Injections in Infants.—Ann Martin (*Brit. Med. Jour.*, July 8, 1916) finds that the plan of injection into the superior longitudinal sinus, as suggested by Helmholtz, has proved perfectly safe, satisfactory, and easy of performance. As performed by Martin the scalp over the anterior fontanelle is shaved and painted with iodine. The child's head is raised on pillows to a convenient height and held by a nurse. Standing on the right side of the child a short, sharp needle with very short bevel is pushed through the fontanelle in the middle line at a point half way between the superior angle and the middle of the fontanelle. The needle should be held at an angle of 50° to 60° with the plane of the fontanelle. The tip should not penetrate over one eighth of an inch, when it will be found to be in a cavity from which blood can be withdrawn at will. No anesthetic is used in the operation. This method can be used for the removal of blood for examinations or for the administration of drugs in solution and the puncture may be repeated as often as necessary.

Intramuscular Use of Corpus luteum Extract in the Surgical Menopause.—John C. Hirst (*American Journal of Obstetrics*, April, 1916) states that in the surgical menopause his results from the oral administration of corpus luteum extract have been disappointing. The large doses necessary for beneficial effects are often productive of nausea. He has lately tried, however, intramuscular administration of the drug, with gratifying results. In the first case reported, after discontinuance of oral administration on account of nausea, with only slight amelioration, intramuscular injections equivalent to fifteen grains of fresh gland were given, at first daily for eighteen doses, then on alternate days for four weeks, and later biweekly for a few weeks. The flashes of heat and other symptoms began to improve rapidly after about six doses, without nausea, and since the end of the treatment the patient has remained practically free of symptoms. Similar results were obtained in five other cases of supravaginal hysterectomy. Hirst believes the doses he used could be greatly increased with benefit and without harmful effect. Experience will probably show the effect of the drug to be cumulative, and that the interval between doses can be gradually lengthened and the drug then discontinued without a return to the previous symptoms.

Treatment of Thoracic Empyema.—Howard Lilienthal and Martin W. Ware (*N. Y. State Jour. Med.*, July, 1916) report that under routine methods of treatment mortality remained nearly constant. With greater individualization in method a marked reduction in mortality became possible. Success in the treatment was found to rest largely upon accurate diagnosis of the exact location, severity and extent of the condition. Where the patient was extremely ill, a simple thoracotomy, between two ribs, with insertion of a drainage tube was done as the initial operation. Later, when conditions were favorable, the chest was opened by division of the intercostal muscles and by retraction of the ribs to expose the greater part of the interior of the pleural cavity and permit complete evacuation of the pus and liberation of the lung from its confinement in thickened pleura, thus permitting it to expand and fill the chest without the production of deformity. The incision of the thickened pleura to liberate the lung often disclosed unsuspected pus pockets which were also evacuated, and with the aid of the x ray other pockets were located and all were opened. Following such an operation the wound was closed, room for drainage alone having been left. Under such treatment many cases were cured without secondary deformity from sinking in of the chest wall, and general mortality was greatly lowered through elimination of septic absorption from unopened foci of purulent inflammation.

Reactionless Intravenous Milk Sugar Injections.—W. Wechselmann (*Berlin. klin. Woch.*, January 24, 1916) has found by experience that the intravenous injection of lactose for the purpose of the Schlayer test is often followed by a marked reaction with chills, fever, and vomiting. Investigation showed that this reaction did not occur when the milk sugar was freshly prepared and had been kept dry and sterile. The reaction was proved to be due to growth in the lactose of a fungus, which, however, was not readily detectable and which might be present in an apparently fresh specimen of ordinary lactose. With these facts in mind the author suggested the preparation of lactose under sterile conditions and its immediate solution in freshly distilled water. The fresh solution, containing ten per cent. of milk sugar, should then be filled into twenty mil ampoules, sealed, and sterilized. This suggestion was adopted commercially and a preparation of lactose has been placed on the market under the name of renovasculin which may be used for the Schlayer kidney function test without danger of reaction.

Treatment of Vesicular Eczema.—P. G. Unna (*Berlin. klin. Woch.*, Jan. 24, 1916) states that the deep vesicles on callous portions of the hands often cause great distress from itching and resist usual forms of treatment with drying applications. Such treatment must be preceded by the application of agents to soften and exfoliate the overlying horny layer, the most satisfactory application having proved to be rubber plaster impregnated with ichthargan. Even ordinary scaly eczema at times requires exfoliative and softening agents, but these are usually too painful for use. Baths and soaps are far more satisfactory. If there is much itching the baths must be given only moderately warm —always below 30° C.—and of brief duration in order not to produce a vascular reaction. Rubbing must also be avoided and the skin is dred by mopping. The application of a powder such as talcum or magnesium carbonate after the drying often relieves the tendency to itching. If the itching is severe, bran may be added to the bath or from fifty to 100 mils of each of the following solutions:

A. Tannic acid, ... 10.0
Distilled water, to.....100.0
B. Sulphate of iron,..... 20.0
Distilled water, to.....100.0

The use of the latter, making the so called ink bath, is not sufficiently appreciated. It not only allays itching and inflammation, but is decidedly sedative and prevents maceration of the epidermal layer.

Case of Multiple Cartilaginous Exostosis.—H. W. Marshall (*American Journal of Orthopedic Surgery,* June, 1916) reports a case of multiple osteochondromata. Numerous photographs and x rays show growth on many bones of the body. An examination of one of the growths showed it to be benign in character. There was a significant family history in this particular case.

Infected Conjunctiva.—Walter B. Lancaster (*Jour. A. M. A.,* July 22, 1916) in the course of a discussion of the preparation of the eye case for surgical operation, makes some useful suggestions for the treatment of infection of the conjunctiva. Drainage and irrigation should be prescribed to remove mechanically the bacteria as fast as possible. Hourly instillation of a twenty to twenty-five per cent. solution of argyrol in sterile water and free irrigation two or three or more times daily, with a one to 5,000 solution of mercuric cyanide or chloride will accomplish this purpose. The frequent application of strong irritants, however, is not advisable and the following bland lotion is very satisfactory to replace them:

Boric acid,	0.8;
Borax,	8.8;
Oil eucalyptus,	0.15;
Oil wintergreen,	0.15;
Menthol,	0.050;
Thymol,	0.075;
Water,	1000.0.

The general and local resistance of the patient should be increased by proper dietetic and hygienic measures, and in suitable cases vaccines may be of considerable value, but their field is not yet well defined.

Infection of the Uterine Appendages.—E. E. Montgomery (*N. Y. State Jour. Med.,* July, 1916) makes a strong plea for early diagnosis and treatment along medical lines with as little surgical interference as possible, as thereby many a case can be cured without the sacrifice of organs or material impairment of their functions. In early cases, particularly of gonococcic infection, the woman should be put to bed and the vagina irrigated every two or three hours with two per cent. phenol, one in 4,000 bichloride of mercury, or thirty minims of Lugol's solution to the pint. These irrigations should be hot and the vulva should be kept covered between treatments with a pad moistened with three per cent. phenol or twenty per cent. alcohol solution. The bowels should be kept open and an abundance of water given the patient to drink. If there is evidence of pelvic involvement, ice bags should be continuously applied to the abdomen. On the subsidence of acute symptoms hot applications should be used to promote absorption and destruction of the infecting organisms. In addition it is well to cleanse the vagina through a speculum and paint it with tincture of iodine or a two per cent. solution of silver nitrate. After this it should be packed with iodoform gauze. Pus in the pelvic cavity should be evacuated, if possible, through vaginal incision and drainage, and even when laparotomy is required the infected parts should be conserved as much as possible, for they will often recover if placed in a favorable position and their function will be preserved.

Malta Fever.—Bernardino Luighetti (*Riforma medica,* June 26, 1916) gives an exhaustive résumé of the literature of this disease, and concludes that the anatomical findings show nothing characteristic, but, rather, are those seen in the more common septicemias.

Optochin in Pneumonia.—J. Manliu (*Berlin. klin. Woch.,* January 17, 1916) reports twelve severe cases of pneumonia treated with optochin, with recovery in ten and death from complications in two. Five of the patients did not begin treatment until after the third day of their disease. The dose used was 0.25 gram every four hours day and night until the temperature reached normal, after which one additional dose was given. The effects of the drug were manifest in the rapid reduction of the fever, marked quieting of the patients, and diminution in the dyspnea. The drug did not seem to have any effect on the symptoms of intoxication. The highly conflicting results reported by many other authors are reviewed in this paper, and the conclusion is reached that the drug must be administered with care and stopped as soon as the first symptom—tinnitus—of its toxic effects becomes manifest. If this is done, there is little danger of causing serious intoxication. The administration of camphor seems to be of value in overcoming the toxic effects of optochin when these have made their appearance. It is not enough to restrict the medication in pneumonia to the use of optochin, but all other drugs, such as camphor, digitalis, morphine, etc., should be employed according to their indications. Finally the standard dose of 0.25 gram, four hourly, day and night, should not be exceeded.

Treatment of Cold Abscesses.—E. A. Rich (*Northwest Medicine,* July, 1916) states that if the abscess is a small one the absolute rule must be, "hands off." The indication is for the employment of greater mechanical fixation of the diseased portion of the bony system and enforced physical rest. The only indication for resort to surgery in the case of a cold abscess is when it becomes so large as to produce unendurable pain from pressure. Then the only allowable procedure is aspiration of some of its contents under the most rigid conditions of asepsis possible. The aspiration should always be done with a moderately large needle; never with a trocar and cannula. The needle should be inserted into the abscess cavity obliquely to secure perfect closure of the tract after its withdrawal. In this way we need never fear the subsequent development of a sinus. Following aspiration the abscess should be subjected to some degree of pressure by bandaging, in the hope of delaying the refilling of its cavity. Incision of a cold abscess absolutely dooms it to infection with all of the dire consequences from chronic sinuses through amyloid disease to death. Even retropharyngeal abscesses should be drained only through aspiration. In very chronic cold abscesses cure is not infrequently possible as a result of repeated puncture and complete aspiration with suction. Many abscesses of this nature will undergo complete cure when the bony parts are completely immobilized and the patient is treated for his osseous tuberculosis.

Miscellany from Home and Foreign Journals

Poliomyelitis with Its Preparalytic Symptoms.—Louis Fisher (*Medical Record*, July 29, 1916) describes two preparalytic symptoms, the first of which, described by Draper, is the production of pain and stiffness of the neck on flexion of the spine anteriorly. Another symptom, described by Culliver, is a twitching, or convulsive movement, affecting one or more limbs, the face or the jaw, which is sometimes accompanied by a peculiar cerebral cry. Three types of poliomyelitis are met with: the catarrhal, the gastrointestinal, and the cerebral. Abortive cases are most common, and from their mildness are overlooked by the laity and so spread the disease.

Prognosis in Infantile Paralysis.—Walter G. Stern (*Journal A. M. A.*, July 29, 1916) calls attention to the great amount of harm done by the medical profession in connection with this disease in making an incorrect prognosis. Whatever may be power with a more or less imperfect functional recovery, the prognosis should always be guarded, conservative, and truthful. If too much hope is given, the parents may be disappointed, and sacrifice all of the gain in strength in seeking a perfect cure. It should be remembered that the majority of patients make only an incomplete recovery of muscular power with a more or less imperfect functional result. Spontaneous recovery reaches its maximum in from three to six months, but careful treatment with physiological rest of the affected parts, graded massage, electrical stimulation, resistance exercises, and muscle training not only improve the chances of partial recovery, but also prolong indefinitely the period in which further recovery may take place. The most harmful influences and those most likely to impair the ultimate result are misuse, overwork, overstimulation, and overexertion, with resulting contractures.

Pleuropulmonary Complications in Wounds of the Central Nervous System.—G. Roussy (*Bulletin de l'Académie de médecine*, June 13, 1916) calls attention to the frequency of inflammatory complications in the lungs or pleuræ as the lethal factor in wounds of the skull or spinal cord. Fever and impaired general condition in such cases have generally led to suspicion of an inflammatory lesion of the brain or its meninges or to a diagnosis of infectious myelitis or meningomyelitis. Roussy reports, however, cases of spinal and skull injury in which empyema caused death, and other spinal cases in which bronchopneumonia supervened. In none of these cases were acute inflammatory changes found at autopsy in the meninges, cord, or brain. Patients with major nervous wounds should be considered eminently frail, sensitive to cold, and liable to dangerous injury from even brief transportation. They are also profoundly shocked, and should be promptly stimulated with saline injections and camphorated oil. They should be kept in bed as long as possible and the respiratory system examined daily, especially when fever appears.

Hysterical Mutism in a Boy.—Arthur J. Hall in the *Lancet* for May 20, 1916, describes a boy of eleven years in whom fright and fear of an operation for diseased tonsils and adenoids produced a condition of mutism which lasted five weeks and was cured by another fright in the hospital ward after all treatment had failed.

Syphilitic Infection from Toilet Soap.—M. L. Heidingsfeld (*Lancet-Clinic*, July 8, 1916) reports the case of a man of forty years presenting a well defined roseola, general glandular enlargement, and characteristic facial erythema in whom all efforts to find the initial lesion were fruitless, except in that a pigmented node, with characteristic indurated base, was found on the back of the neck. Two months before, the patient had had a boil there, and had make a poultice of soap and water from his five cent cake of lodging house soap and applied it to the boil for several nights. Extragenital infection in this case is considered traceable to the use of infected soap, and is held to be an illustration that common employment of toilet soap is not devoid of the risk of transmission of syphilitic infection.

Role of the Tonsil in the Production of Appendicitis.—S. C. McCoy (*Lancet-Clinic*, July 15, 1916) thinks it now established on an experimental as well as a clinical basis, that appendicitis is at times of hematogenous origin. The clinical relationship of appendicitis and tonsillitis does not, however, depend for its acceptance on the theory of a hematogenous origin. It has been shown by Chastenet that appendicitis can be produced in rabbits by feeding pathogenic bacteria; the possibility of infection from the tonsil by way of the alimentary tract is, therefore, apparent. Isabolinsky has shown the relative unimportance of colon bacilli alone in the causation of appendicitis. McCoy presents data from the literature illustrating plainly the role of acute tonsillitis as a forerunner of appendicitis.

High Palate and Adenoids.—W. Lublinski (*Berlin. klin. Woch.*, January 24, 1916) calls attention to many cases of adenoid hypertrophy which are not clinically benefited by thorough removal of the hypertrophied masses. In such cases a high vaulted and much narrowed hard palate will be found. Nasal examination will show that the elevation of the floor of the nose has been such as to allow the inferior turbinates to meet its upper surface and occlude the air passages. In such a case the removal of adenoids accomplishes practically nothing and the patient still remains a ready victim to infection of the middle ear, continues as a mouth breather, and is retarded in mental and physical development. Before adenectomy a careful examination of the palate and the nasal cavities should be made, and if the condition just described is found, mechanical means should at once be instituted to bring about a widening of the palate with consequent lowering and freeing of the nasal passages. Then adenectomy will give complete relief.

Cerebrin in Treatment of Cerebral Neurasthenia.—J. S. de Figuera (*Revista de Medicina y Cirurgia Practicas,* July 8, 1916), having tried cerebrin or cerebral extract in six cases finds that, when freshly prepared, it exerts a beneficial action on the headache, vertigo, insomnia and nervous agitation of cerebral neurasthenics. While it may be given by mouth, it is better given hypodermically daily for several months.

Treatment of Cholera.—Stafford M. Cox (*Lancet,* July 1, 1916) thinks that serum treatment offers little if any hope, and is probably even harmful through the further liberation of endotoxins and a consequent increase in symptoms. The greatest utility of this form of treatment lies in its possible prophylactic value. The most dangerous and most difficult stage of cholera to handle is collapse. This can best be treated by the intravenous injection of large amounts of salt solution. Contrary to the views of Rogers, good results follow the use of normal saline solution instead of the hypertonic solutions. Further experience has shown that the best results can be secured by the initial administration of hypertonic saline until from seven to eight pints have been given, and then by continuation of the injection, using normal saline. The rate of injection should be slow—about two ounces a minute, and the saline should be continuously given until a rise of temperature to 103° F. or less, accompanied by a rigor, has been produced; then the injection should be continued until a total of eight to ten pints have been given, the rigor having come on usually after about five pints. By this plan the blood is diluted, the blood pressure raised, the renal excretion restored, elimination of the endotoxins secured, and the subsequent course of the disease is made apyrexial.

An Experience of Galyl.—Sheldon F. Dudley (*Lancet,* July 8, 1916) substituted this comparatively new arsenical for neosalvarsan during the shortage of the latter drug and about 1,500 injections of each of the two drugs have now been made and offer opportunities for a close comparison of the virtues and shortcomings of each. The doses used were 0.4 gram of galyl or 0.9 gram of neosalvarsan and the methods of use and additional treatment were the same for both drugs. Galyl was found to be decidedly less toxic, as revealed by far less likely to be followed by reactions than the first ing its use than after neosalvarsan. In the case of both of the drugs subsequent injections were always less frequent vomiting, headache or fever follow- Neosalvarsan seemed to have slightly more power to produce negative Wassermann reactions than galyl, and also was more effective in preventing early negative reactions from becoming positive. The two drugs removed the spirochetes from open sores equally efficiently, though neosalvarsan acted slightly more rapidly. In general, galyl seemed to be about as satisfactory clinically as neosalvarsan. Since galyl is decidedly less toxic than neosalvarsan, and since the dose used contains just half as much arsenic as that of neosalvarsan, it is suggested that better effects might be secured from the administration of somewhat larger doses. [Galyl is not obtainable in this country.—Eds.]

Digitalis and Physostigmine as Hypotensor Remedies.—D. Danielopolu, at a recent meeting of the Biological Society of Bucharest (*Presse médicale,* June 5, 1916), stated that prolonged observations in thirty-two cases had convinced him that digitalis never raised, but often lowered, the blood pressure. Its hypotensor action seems to be more marked if a suitable dose of physostigmine has previously been administered.

Prognosis in Pulmonary Edema.—T. F. Reilly (*Archives of Diagnosis,* April, 1916) points out that there are many cases of mild pulmonary edema without frothy expectoration nor much dyspnea, in early cases of cardiac decompensation; in these instances the prognosis is good provided, as is almost always the case, that decompensation can be overcome by treatment. Pulmonary edema in the course of apoplectic strokes, when it occurs within the first few hours, may be recovered from; when after the second day it is always fatal unless there is an accompanying cardiac lesion. Pulmonary edema occurring during or after a uremic convulsion is frequently recovered from, especially if the patient regains consciousness within two or three hours. Absence of a very high vascular tension, as well as excretion of a moderately large amount of urine, improve the outlook. Pulmonary edema occurring in the course of toxic states is most frequent in pneumonia. While generalized edema developing late in pneumonia is always fatal, edema developing early —an accident especially frequent in old patients— will often clear up for a few days under active stimulation, though death generally follows later. The pulmonary edema occasionally met with in middle aged patients from alimentary toxemia, usually associated with an underlying renal process, is followed, as a rule, by recovery, though death may seem imminent for a time. In the recurring pulmonary edema of cardiovascular disease, the average duration of life after the first attack in Reilly's cases was about two years. These patients do not generally die during the attack itself, although death occurs in some within the first five or ten minutes. A fall of pulse tension early during the attack affords a serious outlook; when it falls later, however, with coincident respiratory and other improvement, it is a good sign. The outlook in cases without expectoration is no worse than in others. A clanging second sound at the right of the sternum is a favorable sign, but intense vascular phenomena are unfavorable. The average duration of untreated attacks is three or four hours, but under active treatment the paroxysm is over in an hour or two, and the physician may leave half an hour later. Pulmonary edema resulting from the use of pilocarpine or following head injuries is rarely recovered from; in that associated with angioneurotic edema or following thoracic paracentesis on the other hand, the prognosis is good. From pulmonary edema after ether anesthesia, about fifty per cent. seemingly recover; the diagnosis is, however, delicate in these cases. In the pulmonary edema seen during infantile convulsions the outlook is good, the trouble disappearing within an hour or two after the return to consciousness. In that accompanying infectious diseases in children, however, death usually occurs within a few hours.

Nitrous Oxide—the Most Dangerous Anesthetic.—J. F. Baldwin (*Medical Record,* July 29, 1916) insists that this form of anesthesia is not nearly so safe as chloroform, which has always been considered dangerous. He quotes fourteen deaths which are known to have occurred in Columbus alone. Postoperative pneumonia, often attributed to ether, is due to peritoneal infection carried to the lungs and also to poor pulmonary ventilation in laparotomy cases, owing to the limitation of movement of the abdominal muscles. The field of anesthesia by nitrous oxide-oxygen gas is limited to extraction of teeth, and in cases of acute pulmonary congestion or of acute nephritis.

Treatment of Delayed Callus Formation and Pseudarthrosis with Fibrin Injections.—S. Bergel (*Berlin klin. Woch.,* January 10, 1916) reports that animal experimentation with the various constituents of the blood showed that fibrin had a direct stimulant action on the processes of healing. When injected subperiosteally in normal animals it caused the development of exostoses. Applying these observations to human therapeutics, the author employed a purified fibrin, in the form of a fine emulsion, for injection into the region of ununited fractures, pseudarthroses, etc., and found that it materially shortened the period of healing and ossification. The dose usually used was 0.3 gram suspended in ten c. c. of normal salt solution, to be repeated every two, three, or four weeks if required. The injections produced slight constitutional symptoms, such as headache and moderate elevation of temperature. The local reaction was more marked and consisted of edema, which lasted a few days. It is recommended that this form of treatment be employed early in fractures which do not seem to be healing well, since it is simple and harmless.

Perforated Ulcers of the Stomach and Duodenum.—Raymond P. Sullivan (*Jour. A. M. A.,* July 29, 1916) has analyzed a number of cases and concludes that an early diagnosis of either of these conditions should be possible. The treatment should be surgical and should be undertaken immediately. The most characteristic symptoms of perforation are, in the order of their frequency: Abdominal pain, tenderness, vomiting, muscular rigidity, previous ulcer symptoms, anxiety and restlessness, increasing pulse rate, and rise of temperature. The pain and tenderness are commonly in the upper abdomen and usually in the right hypochondrium. The pain is intense and unyielding. Sometimes pain and tenderness may suggest acute appendicitis from the location. Rigidity increases as the time after perforation lengthens, and is usually boardlike. There is little rise in temperature, and the pulse rate usually increases out of proportion to this; the respiration is usually thoracic and is strikingly accelerated. Such symptoms, occurring in one who has had the symptoms of ulcer for some time previously, should make the diagnosis of perforation almost certain, and when such symptoms are present, the physician should not delay for observation or for more accurate diagnosis, but should at once invoke the aid of surgery.

Chronic Purulent Otitis media, With Special Reference to Tuberculosis, by Wendell C. Phillips.—The author believes from clinical evidence alone that primary local tuberculosis of the soft tissues, ossicles and bony walls of the middle ear is the determining factor in the large proportion of all persistent otorrheas, especially in young children.

Total Esophagoplasty.—G. Axhausen (*Berlin. klin. Woch.,* January 17, 1916) gives a detailed report of the various steps taken in this rare operative venture in an account of his treatment of a case of traumatic esophageal stricture. Briefly summarized they comprised a gastrostomy and an intestinal anastomosis between a portion of the small intestine and the upper part of the stomach. The length of small intestine thus united was freed from all attachments save its blood supply, and its opposite free end was carried up toward the ensiform beneath the skin of the abdomen. The remaining small intestine was reunited by lateral anastomosis. A tube was then made down the thorax over the sternum by rolling a strip of skin together so as to bring the epithelial surface inward. This was then covered by the skin from either side. Next the upper end of the esophagus was freed from its attachments, brought forward and united to the artificial skin tube, which was in turn united to the tube made previously from the length of small intestine. The ultimate result was that in a few months the patient had returned to his ordinary diet and suffered no difficulty in swallowing all forms of food.

Pseudappendicitis. — F. Gregory Connell (*Jour. A. M. A.,* July 29, 1916) has analyzed a large number of cases operated in for chronic appendicitis or as interval cases, and found that forty-eight were not relieved of symptoms and there was no rational explanation of their persistence. From this observation and close analysis of all of the cases operated in with this diagnosis, the author questioned the existence of such a clinical entity as chronic appendicitis. Certainly the diagnosis was often incorrect and was made with unwarranted frequency. When all demonstrable pathological conditions which might possibly be confounded with a chronic appendicitis were eliminated, there still remained a number of cases in which complaint was made of pain in the right iliac fossa. These cases might better be classed as pseudappendicitis and were present usually in persons with visceral ptosis, constipation, and neurasthenia. This condition did not call for surgical treatment, but was a strictly medical condition. The difficulty of making a correct diagnosis of these pseudappendicitis cases was great, but every case conforming to the type should be considered as having this condition until careful investigation proved the contrary. The typical features of this group were more or less continuous pain in the right side of the abdomen, mild, but short attacks with short intervals of freedom. The pain was made worse by exercise and was relieved by recumbency. There were cutaneous hypersensitiveness, muscular spasm, gas tumor, cæcum mobile, gurgling, nausea, normal or subnormal temperature and no leucocytosis. Vomiting was rare. The patients often became chronic invalids.

Proceedings of National and Local Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-first Annual Meeting, Held at Washington, D. C., May 9, 10, and 11, 1916.

The President, Dr. J. Wesley Bovee, of Washington, D. C., in the Chair.

Syphilis in Its Relation to Obstetrics.—Dr. Edward P. Davis, of Philadelphia, stated that modern knowledge on this subject dated from the discovery of Spirochæta pallida in 1905-6 as the cause of syphilis. The discovery of the Wassermann reaction as a means of diagnosis, and salvarsan in treatment, were also important factors. Syphilis could be positively diagnosticated in a newborn infant by the characteristic germs in the blood taken from the umbilical vein and from the tissues about the umbilicus and umbilical cord. Examination of the bodies of infants dying soon after birth from syphilis, showed this germ abundantly present in the important organs. A woman apparently healthy giving birth to a syphilitic infant was herself syphilitic, although she might show for some years no clinical signs or symptoms. In these cases syphilis was conveyed from the ovum to the mother through the medium of the placenta. The mother was said to have latent syphilis and could nurse her child without disturbance of her own health, and with positive benefit to the child. She might, however, at any time manifest symptoms of secondary or tertiary syphilis.

The Wassermann reaction was untrustworthy as a positive test for syphilis in parturient women. It might give a positive reaction in severe toxemia and eclampsia where syphilis was absent, and in some other conditions where the mother's general health was seriously disturbed. In the lack of a more reliable means of diagnosis, the Wassermann test should invariably be made in selecting wet nurses, and in all suspicious cases.

Syphilis in the acute stage attacking a pregnant woman could often be promptly checked by salvarsan. While the germs causing syphilis would be destroyed, the toxins which they produced would usually cause death of the fetus. If syphilis occurred early in pregnancy, the best result for mother and child would be obtained by mercurial treatment accompanied by potassium iodide. Where skin lesions were present, hypodermic or intravenous injections of mercurial solutions were useful.

In treating active syphilis in the newborn, salvarsan had been given in the cubital vein with good results. Where salvarsan was used with mother and child, the urine of the patient should be repeatedly examined to determine the presence of arsenic, and the presence of signs of irritation of the kidneys. Should traces of arsenic disappear from the urine, arsenical poisoning might be feared.

Syphilis in parturient women greatly increased the mortality and morbidity for the mother through mixed infection and lesions of the genital organs. Unless promptly detected and treated, it was one of the most important causes of fetal death. No syphilitics should be allowed to marry unless they had been under observation for six years after the last appearance of symptoms.

Syphilis in Relation to Some Social Problems.—Dr. Sigmund Pollitzer, of New York, dealt with three distinct subjects; first, hereditary syphilis in the light of today. The fact that syphilis could be transmitted from the syphilitic mother to her unborn child was recognized four hundred years ago; but the fact that syphilitic children were born of apparently healthy mothers led to the conclusion that syphilis might be transmitted to the offspring by way of the semen of the father without infecting the mother. In fact, paternal syphilis was regarded as the most frequent form in syphilitic heredity. More extended and definite clinical observation, the discovery of the spirochete on the maternal aspect of the placenta, and the results of the Wassermann test had completely changed their views in this respect. Transmission of spirochetes to the ovum might be regarded virtually as a physical impossibility; a spirochete was three times as long as the diameter of a spermatozoid head, and, furthermore, an infected ovum would not develop into a fetus. Colles's law and Profeta's law were true only in the sense that the mother of a syphilitic child and the child of a syphilitic mother already had syphilis, and therefore apparently could not acquire it. The apparently healthy mothers of syphilitic children invariably had a positive Wassermann reaction and generally presented symptoms of syphilis if they were followed up long enough. The failure to show a history of the infection in these cases was not remarkable in view of the statistics of syphilis in women; in only about one third of the cases that were seen with definite tertiary lesions could a history of infection be elicited. The speaker would emphasize the importance of making a Wassermann test in every case of unexplained abortion, instead of resting content with the inadequate explanation of deflections, adhesions, etc.

When May the Syphilitic Marry?—Doctor Pollitzer presented this paper also, and said recent progress had greatly changed their views on the gravity of syphilis, especially with reference to lesions of the heart and central nervous system, and at the same time had greatly improved prognostic and therapeutic possibilities. The question of the medical sanction to marriage of the syphilitic had been most earnestly considered forty years ago by Fournier, and the principles laid down by him had been generally followed. The syphilitic might marry when there was a reasonable certainty of his cure. No criterion of cure being possible, formerly a definite period of time and treatment was arbitrarily fixed upon, based on clinical experience. The syphilitic might marry if he had received three years of treatment and had remained free from symptoms for another year or two. Millions of happy marriages proved the wisdom of the rule, but the thousands that resulted in infection of their wives and the birth of syphilitic children proved its inade-

quacy. The Wassermann test afforded a trustworthy criterion of cure.

The syphilitic woman might marry without risk of infecting her husband after she had reached the tertiary stage of the disease, but she could not become a mother without the risk of bearing syphilitic children until she was permanently Wassermann negative.

The Control of Syphilis.—This was Doctor POLLITZER's third paper. The attempt to control the incidence of syphilis by segregation, he said, had proved of slight value and, moreover, in Anglo-Saxon countries met with too much prejudice to permit of its enforcement. The control of syphilis must come through education of the public in the risks and dangers of illicit intercourse, and education of the physician in the importance of early diagnosis and proper treatment. Various educational bodies were undertaking a campaign of instruction in these matters; even the public press, which a few years ago had never printed the word syphilis, today contained educational articles which dealt with the subject frankly. The public was being educated. How far knowledge of the risks and dangers of illicit intercourse would serve as a deterrent was a moot question.

The speaker referred to the excellent results obtained by the prophylactic use of calomel ointment in the armies and navies of the world, a procedure which, if generally employed, would as effectively control the great pox as the smallpox had been controlled by vaccination. He contrasted the generous provision made for the care of the syphilitic in the hospitals of European cities, with the attitude of our American hospitals, to most of which the patient with an active syphilis was refused admission, and concluded with a plea to his hearers to exert their personal influence to the end that better hospital facilities be provided for the syphilitic.

Syphilis of the Internal Genital Organs in the Female.—Dr. GEORGE GELLHORN and Dr. HUGO EHRENFEST, of St. Louis, contributed a joint paper on this subject, saying that syphilis had always been assumed to be considerably commoner among men than among women; but from certain investigations this supposition could not yet be accepted as conclusive. At any rate, syphilis was common enough in women to constitute a gynecological problem in the widest sense. Not every disease in a syphilitic woman was syphilitic in nature, but syphilis, if present, would exert an influence of its own upon coexistent diseases. Latent syphilis prevailed more in women than in men.

The course of syphilis in men differed in many points from that in women. To instance but one of the differences, the relative frequency of tabes and paresis in the two sexes was well known.

Primary chancres of the vagina were rare, probably because of certain histological and biological characteristics of the vagina. Tertiary luetic manifestations of the vagina were also extremely rare. They represented, as a rule, the continuation of secondary lesions in the vulva, uterus, or adjoining organs. The isolated submucous gumma broke down early and appeared in the form of a more or less characteristic ulcer. The more destructive processes which eventually led to the formation of fistulæ and strictures almost always originated in strictures surrounding the vagina. Tertiary lesions of the vagina did not exhibit characteristic symptoms, such as pain or discharge.

The primary chancre of the cervix represented the best known and most common type of syphilitic affections of the female internal genitalia. Its frequency had probably been overestimated. Statistics based on a large number of observations had never shown a frequency over 1.5 per cent. of all primary chancres found on the genitalia. Eight personal observations were added by the authors to the few cases found in the literature of secondary lesions of the cervix. Syphilis manifested itself upon the cervix in the form of macules, papules, and ulcerations. These forms probably represented three successive stages in the development of a lesion caused by scattered accumulations of the spirochete in the squamous mucosa of the cervix. The parasite could readily be discovered in the secretion of any of the three forms, and this explained the great infectiousness of secondary lesions. The Wassermann reaction was positive in this stage.

Syphilis of the pelvic cellular tissue appeared in the form of a diffuse gummatous infiltration which involved the pelvic peritoneum secondarily. To the few cases on record the authors added a personal observation. In almost all instances a diagnosis of malignancy had been wrongly made. In their own case the positive outcome of the Wassermann reaction, together with other unmistakable signs of tertiary syphilis about the outer genitals, aided in arriving at the correct diagnosis. Specific treatment produced amazingly quick improvement in an apparently hopeless condition.

Familiarity with syphilitic lesions in the genital tract must prove of eminent practical value to the gynecologist in view of the frequent confusion in the diagnosis of cancer and syphilitic ulcerations or gummata. That occasionally a patient who could have been cured by antiluetic treatment, was subjected to a serious radical operation, there could be no doubt.

The Specificity of the Wassermann Reaction.—Dr. RUDOLPH BUHMAN, of St. Louis, gave the results of the Wassermann reaction in a series of diseases from patients supposed to be free from syphilis, with special reference to malignant diseases. Of 132 cases of malignant diseases, including carcinoma, sarcoma, and malignant adenoma, nine gave a positive reaction; six of these nine cases were both malignant disease and syphilis; the other three cases were not under observation long enough to permit of diagnosis by the test.

Syphilis in the University of Michigan Obstetrical and Gynecological Clinic.—Dr. REUBEN PETERSON, of Ann Arbor, Michigan, presented the following summary and conclusions: 1. Only by routine Wassermann tests would the obstetrician and gynecologist best serve the interests of his patients. 2. Especially was this true in hospital practice, where even careful histories failed to arouse suspicion of latent syphilis. 3. Out of 2,000 in patients in the University Hospital, excluding two

services, the proportion of syphilitics was six per cent. 4. The nature of the hospital material would determine the percentage of lues, but in the average hospital the ratio would not be far from eight to ten per cent. if the entire hospital population was included. 5. The same held true for the proportion of syphilis in any special clinic, the percentage varying according to the nature of the material. 6. The percentage of lues in 381 cases in the University maternity was 4.7, as shown by the Wassermann reactions and expert physical examinations. 7. In eighteen cases of syphilis among the number examined, only eight, or less than half, gave a history of lues. 8. In only the same number (eight) were there positive physical signs of lues. 9. As shown by the histories of the eighteen cases, there was a greater chance for the syphilitic mother treated by salvarsan and mercury to give birth to a living full term child than where no treatment was given during pregnancy. 10. The newborn infants of the mothers so treated did not give positive Wassermann reactions, although undoubtedly they were syphilitic and later would probably show signs of the disease. 11. A certain proportion of the newborn children of untreated syphilitic mothers would give positive Wassermanns. 12. Out of 390 gynecological patients subjected to the Wassermann test, twenty-two or 5.6 per cent. gave positive reactions. 13. In only five of the twenty-two luetic patients was there a history of syphilis. 14. Hence the importance of such examinations, or a serious general disease would be overlooked and the gynecological patient would remain uncured.

How Closely Do the Wassermann Reaction and the Placental Histology Agree in the Diagnosis of Syphilis?—Dr. J. Morris Clemons, of New Haven, Conn., stated that in 360 consecutive confinements the Wassermann test had been made on the mother's blood and the placenta had been studied for evidences of syphilis. The most notable disagreement occurred in cases of toxemia of pregnancy, which not infrequently presented a faintly positive Wassermann reaction, though the placenta was normal.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16, 17, and 18, 1916.

The President, Dr. W. Stanton Gleason, of Newburgh, in the Chair.

(*Continued from page 286.*)

The Nauheim Method.—Dr. Simon Baruch, of New York, stated that when he stood three years ago in that room, it had been his privilege to open the boom for the Saratoga baths. He little thought that there would be today facilities for hundreds of carbon dioxide baths in Saratoga, for at that time the only bath here was one tub with city water, supplied with gas from a cylinder. The Nauheim physicians had evolved a specific method of bathing, the success of which had been established during the most enlightened period of medicine, not by the patient's statement, but by observations of specialists all over the world. 1. The Nauheim water contained a supersaturation of carbon dioxide and certain salines, of which sodium and calcium chloride existed in decided quantities. 2. The mineral springs of Saratoga furnished the most important constituent, viz., carbonic acid, but lacked the strong salines.

Unfortunately the Nauheim method of bathing was rarely administered in this country correctly. The Nauheim bath consisted chiefly of carbon dioxide produced by acids and bicarbonate of sodium, the salines being either omitted or replaced by a few pounds of salt, natural brine or sea water, or as in one large institution, by sodium chloride and bicarbonate of sodium. In some resorts the gas came from a cylinder. There was a lack of precision in giving this bath, which could be obviated only by understanding the physiological action of the gas and salines contained in the Nauheim waters.

The principles of hydrotherapy must be applied judiciously to obtain a vascular training, to raise the functional efficiency of the heart. In Nauheim the highest grades of circulatory insufficiency, with dropsy, etc., were declined. The rationale of the Nauheim bath might be divided into that of the action of carbon dioxide and of the salines. Carbon dioxide produced a sensation of prickling and warmth. The skin was covered with gas bubbles, which protected it more or less against temperature impressions.

1. A cutaneous hyperemia was produced, not through reflex action as after cold procedures, but due to a specific mechanical chemical irritation by the gas. This was proved by the hyperemia being confined to submerged parts. 2. The cutaneous sensibility was heightened, intensifying temperature sensation, whether below or above the point of indifference.

He used the artificial bath in typhoid fever, when the Brand bath was refused or contraindicated, with valuable results. He insisted that the gas was absorbed through the skin and produced a systemic effect, enhancing respiratory activity, which unloaded the right heart and prolonged the diastole. That the absorbed gas also stimulated the unstriated coats of the cutaneous arteries and the heart muscle itself was proved by the fact that animals killed with gas died with the heart in systole. These combined effects prevented those stases which were usually lethal in cardiac diseases.

The temperatures used in the Nauheim baths here were much higher than those at Nauheim. In one large institution the first series was given at a temperature of 98° F., which must damage a defective heart. He had shown long ago, that no vasomotor action occurred after the Nauheim bath unless its temperature was reduced below the point of indifference, which was about 94° F., for carbon dioxide water. Ottfried Miller and his school had confirmed his findings.

Rarely was a lower temperature than 86° F., prescribed by Groedel and others in Nauheim, and the highest was 95° F. The former produced some reflex vasomotor effect, according to Baruch's hydrotherapeutic law, viz., the degree of difference between the water and skin temperature governed the intensity of peripheral excitation and therefore of the vasomotor action. A carbonic acid bath of 94° F., would be indifferent to the skin, while a

bath two to seven degrees lower, which was not uncommon in Nauheim, would produce thermic excitation, resulting in vasomotor effect.

There was no doubt of the superiority of the natural water over the artificially prepared in cardiac diseases, but close attention to detail might make the artificial a good substitute for home use. The Saratoga waters contained from thirty-three to thirty-five per cent. supersaturation, while the artificial baths contained from five to seven per cent. The combination of the resistance at the periphery with the direct stimulation of the heart muscle by carbon dioxide drove the blood with more energy to all the outlying districts, giving the heart a mild training, which produced salutary conditions in the entire vascular system. The action of the salines rested upon a scientific basis. They were not absorbed, but they assisted in the penetration of gas through the skin.

Doctor Baruch advised the authorities at Saratoga to add a definite quantity, twelve pounds of sodium and one pound of calcium chloride, which was the average of the three Sprudels used in Nauheim, to render the Saratoga waters equivalent to the Nauheim waters. Physicians prescribing Nauheim baths should assure themselves that this had been done. By this arrangement the exact formula of the Nauheim waters would be obtained by physicians and could be modified definitely as was done at Nauheim. The physicians, at the latter place, began with two or more thermal baths, which contained the salines. with a minimum of gas. But Groedel had substituted for this complicated formula a simple dilution of fifty per cent. with "sweet water." It would be a simple matter to imitate this procedure in the Nauheim method, in the artificial bath.

All patients should be advised to rest in a recumbent posture for a few days after the journey; in positive insufficiency of the circulation, without great dyspnea, in the recumbent posture. The first series of baths should be with Hathorn No. 1 and added salines, diluted with seventy per cent. plain water at a temperature of 93° F., duration six to eight minutes and repeated every other day. This should be followed by a rest of one or two hours in bed. The patient should be conveyed in a wheel chair or other easily running vehicle to his lodgings. After these baths, the duration might be increased to ten minutes and dilution diminished from time to time. If dyspnea and other manifestations were relieved, the temperature of each bath might be gradually reduced as far as 91°F., and the full salines and gas given. The number and frequency of baths must be ordered in accordance with the effect of the series, ascertained by the report of the nurse, or better still by the physician himself. The prevailing mode of ordering a series of eighteen baths was unscientific and unjust to the patient.

If the cardiac insufficiency was more recent, or compensation appeared to be initiated, the full strength of the salines and gas might be administered for three baths at 93° F., and gradually reduced in temperature, duration increased up to twelve minutes, omitting the third day. The strongest bath was indicated in uncomplicated mitral insufficiency. In the absence of cardiac muscular degeneration, the temperature of each bath might be reduced gradually as far as 86° F., according to its effect upon the pulse and general manifestations. In aortic or mitral stenosis and in cases showing much fibrillation, the bath temperature should never go below 90° F. If palpitation or slight dyspnea occurred only on decided prolonged exertion, or during stair climbing, they might begin at once with the gas and saline bath fifty per cent. and gradually proceed to the strongest bath at 95° F., duration ten minutes, but not exceeding fifteen minutes. Only well ascertained tolerance after each bath warranted lower temperature, which always demanded shorter duration.

In so called fatty or weak heart with feeble compressible pulse at eighty or over, or increased by ordinary exertion, the bath should be gradually increased from the mildest to the strongest. Temperature might go as low as 85°. In arteriosclerosis therapeutic indications were conditioned upon the presence of the high pulse tension and increased blood pressure. The physician should be guided by the effect of each bath. A full bath of Hathorn No. 1, at 93° to 95° F., with saline addition was ideal in such cases, duration being gradually lengthened up to fifteen minutes under careful supervision. In true angina pectoris, Groedel advised refraining from gas baths if amyl nitrite did not relieve the paroxysm. In false angina pectoris, the baths of Hathorn No. 1, Lincoln and Empire Springs without salines were useful.

Neurasthenics suffering from cardiac disturbances were benefited by any gas bath without salines. Purely anemic patients would be favorably influenced by pure gas baths without salines, beginning at 90° F., at five minutes and increasing to eight minutes slowly, going lower, provided that an agreeable reaction followed.

The most favorable time for the bath was in the morning, about an hour after breakfast. While in the tub, the patient should be quiet and avoid inhalation of the gas, which was more apt to occur in the artificial than in the natural water. He should be dried gently, without friction, except in the first two baths, with warm linen sheets or towels, and rest in bed, in a well ventilated room for one or two hours, after each bath. A fairly strong patient, whose pulse was not easily excited might walk slowly to his lodgings, but the majority of patients were advised to ride to their residence.

The object of all treatments was mildly to raise the responsive capacity of the heart muscle by withdrawing obstacles to its free action at the periphery, and enhancing the ventricular energy by slow degrees; in other words, to train the heart muscles as they trained the muscles of the arm, with dumbbells, by gradual increase of labor. This was a coarse analogy; no harm could be done to the healthy voluntary muscles by overexercise, whereas the cardiac muscle acted involuntarily and was related intimately to the complicated machinery of the entire body, to which it furnished pabulum for the organic activities. Moreover, they had to deal with a pathological condition of a delicate organ, demanding cautious adjustment.

Renal Tuberculosis. — Dr. Henry Dawson Furniss, of New York, of thirty-three personally

observed cases, in twenty per cent. found a history of other tuberculous lesions, and of these fifteen per cent. were associated with pulmonary tuberculosis. In fifty per cent. of these cases cystitis was the first symptom; in fifteen per cent. microscopical hematuria, which was followed by cystitis. The hematuria was vesical rather than renal in origin. Renal or ureteral colic was seen in fifteen per cent. The cystitis was the most distressing symptom, and caused loss of sleep from frequent urination. Nephrectomy was advised, before extensive bladder involvement had taken place. Pyuria was present in every case. Tubercle bacilli were found in slides in eighty-five per cent., which appeared high, but was probably an understatement.

In all except early cases there was bladder involvement, characteristic of tuberculosis. By the time the patients applied for treatment the lesions were advanced enough to show characteristic changes. These were redness and induration of the ureteral orifice, often with nodular irregularities. With progress of the disease the induration increased, the meatus became more involved, the trigonum retracted, and the ureter shortened. Later, ulceration occurred, and finally the whole bladder became lined with granulation tissue. In cases of long duration the ureter was involved, and in catheterized urine the finding of tubercle bacilli was evidence of tuberculosis of at least one kidney. The general health of these patients was usually good. Most cases were nephrectomized with ligation and division of the ureter. The percentage of postoperative fistulæ was about the same, whether drainage was used or not. Perhaps undrained cases gave better results. It seemed better to excise the ureter through an extra incision, extraperitoneally. Only one death occurred as a result of operation, but this was complicated with pulmonary tuberculosis. About thirty per cent. of postoperative fistulæ had been reported, but this did not seem detrimental to the health of the patients, even though it lasted two years. After operation there seemed to be a typical tuberculin reaction, the exacerbation of other tuberculous processes, and a rise of temperature, this being apparently due to liberation of tuberculous material into the body. About half of the patients seen were between twenty and thirty years of age. It was essentially a chronic disease and seemed to be rather frequent. The prognosis in operative cases was good.

Dr. Alfred M. Wose, of Syracuse, in regard to the cystoscopic examination of these bladders, said it was important to get the cases early because if they delayed sending the cases for cystoscopy the bladder would contract and in many cases it was impossible to make a differential diagnosis of the urinary secretion; in fact, they could not find the ureters. They had then to base their observations on the bladder content and the clinical symptoms.

Dr. Hiram N. Vineberg, of New York, had operated in eighteen cases in twenty years, and the earlier he got the case, the better was the result; the more the bladder was involved, the less benefit the patient would have from the operation. The cystitis would keep up for a year or more if the case was advanced. In any case of cystitis lasting for some time they might suspect tuberculosis.

Letters to the Editors

OUR DUTY POINTED OUT.

New York, *August 2, 1916.*

To the Editors:

In yesterday's issue of a prominent daily newspaper I read a touching story of the first child ever cured by adrenaline injections of the dreadful infantile paralysis. A friend of mine, who knows me to be a great skeptic in regard to the pretended wonderful effects of the remedy, called my attention to the story, convinced that I would hide my face in shame. But instead I told him flatly that the whole story was a fake—*sit venia verbo*—and he called me an incorrigible heretic. The enclosed clipping from today's *Statszeitung*, however, will show you that my missile did not hit far from the mark. Here is that paper's statement and a translation:

ABER SONST STIMMTE DIE SACHE.

Hilfs-Kommissär John S. Billings untersuchte gestern einen Fall angeblicher Adrenalin-Kur. Es stellte sich heraus, dass das, wie es hiess, durch Adrenalin geheilte Kind weder geheilt ist, noch Adrenalin-Injectionen empfangen hat.

OTHERWISE THE REPORT WAS CORRECT.

Deputy Commissioner John S. Billings yesterday investigated a case of pretended adrenaline cure. It turned out that the child alleged to be cured through adrenaline was neither cured nor had received injections of adrenaline.

It is not necessary to dwell upon the injury of spreading false reports of that nature. It brings to the medical profession anything but a strengthening of prestige, which is not any too great; it causes the public bitter disappointment, and drives it into the clutches of quacks and faith healers. Retracting the report does not repair the damage. Those who believe that a few grains of tonsillar tissue in the body or 0.25 diopter of uncorrected astigmatism are a menace to the human race—and practically the whole public has been educated to that belief (New York Medical Journal, July 29, 1916, pp. 202-204)—put more faith into the original report than into its retraction, after the principle *quæ volumus credimus libenter.*

As editors of a great medical magazine, it devolves upon you to expose the deception and, if possible, to cause an investigation to be made into the question in whose interest such false reports are manufactured and spread.

Max Talmey, M. D.

PREPAREDNESS IN THE MEDICAL CORPS.

New York, *August 3, 1916.*

To the Editors:

In this era of preparedness one reads and hears much of what has been neglected in our military service and in our industrial mobilizing of transportation, etc. As usual, what medical men have accomplished in this line is a closed book.

In Great Britain and in our own country the medical department of the army has shown its foresight, even when the other branches have lagged lamentably. Not long ago, Surgeon General Keogh, of the British army, related to a London medical society that his department had been preparing for a great European war for ten years, having been advised to do so by Mr. Haldane. While the government was unwisely disregarding the late General Roberts's advice to prepare, the surgeon general heeded Mr. Haldane's advice and was ready when the great war opened, very far in advance of all other departments.

Recently I have noted the same wise preparedness in the medical service of the United States army, admonished by the painful and regrettable experience of the Spanish war.

I am led to these remarks by a recent address of Surgeon General Braisted on the remarkable advances in the Bureau of Medicine and Surgery of that service:

During the past two years, the present Secretary of the Navy, in many instances on his own suggestion and in others by his support of the Bureau of Medicine and Surgery, has advanced our service in the following items:

1. He has recommended to Congress the increase of the Medical Corps from 347 to nearly 500, the first increase in twenty years, and most urgently needed.

2. He has provided in his personnel bill a substantial increase in the upper grades of the Medical Corps. No increase in these grades has been made since 1870, notwithstanding the tremendous growth of the service.

3. He has established two Corps Training Schools for

male nurses, and made provision for the increase in this corps by nearly 1,000 men, and has also provided a possible chance for members of this corps to reach commissioned rank, thereby raising the efficiency and esprit of nearly 2,000 enlisted men in the hospital corps of the navy.

4. He has made provision for a new hospital ship for the navy, which will enable us to build the first ship of this kind, designed especially for this purpose, and which will be a model for our country and the world.

5. He has established schools for the training of the native women of Samoa and Guam in nursing, that already are giving most excellent results and are a most important educational effort for these helpless people.

6. He has increased our appropriations to meet our necessities.

7. He has permitted us to take an active part in the regeneration of Haiti by furnishing medical officers and nurses to care for the sanitary needs of Haiti and which ranks with one of our greatest humane efforts.

8. He has supplied already, and gradually will make good our deficiencies in the many large hospital and medical organizations on shore, such as contagious units at Mare Island, Puget Sound, New York, and Newport, and has furnished adequate and commodious homes for our nurses at Mare Island and Boston. We are organizing five Red Cross mobile hospitals of 250 beds, for use at any point on the coast.

9. He has authorized a medical reserve corps of the best medical talent that our country can furnish, to be ready to come to our assistance in time of need, and he is initiating a correspondence school to give these officers a training and working knowledge of their work. He has detailed a number of our best officers for duty in Europe as observers.

Doctor Braisted's comment upon the cause of the solicitude displayed by Secretary Daniels for the medical department is interesting, in that he believes it to be due to the secretary's deep respect and attachment to his family physicians at home.

This fact may furnish a clue to the wiser utilization of the influence of medical men which today is conspicuous by its absence in our legislative halls and elsewhere.

The foregoing are only a few examples showing the interest and activity of our secretary in this branch of the service. Did space permit I should like to continue in detail to show you his interest and help as shown in innumerable questions of sanitation and organization which makes the work of the Medical Department of the Navy one of the most important branches of the service.

SIMON BARUCH, M. D.

Book Reviews

Aids to Bacteriology. By C. G. MOOR, M. A. (Cantab), F. I. C., Captain, First London Sanitary Company, Public Analyst for the County of Dorset and the Boroughs of Poole and Penzance, and WILLIAM PARTRIDGE, F. I. C., Joint Public Analyst for the County of Dorset. Third Edition. New York: William Wood & Co., 1916. Pp. viii-278. (Price, $1.25.)

This little compend contains a wonderful amount of information, well arranged, and specially adapted to readers who want to refresh their memory on the details of bacteriology. The authors have wisely included the pathogenic protozoa, trichomycetes, blastomycetes, and hyphomycetes: there are also sections on fermentation, enzymes, filterable viruses, disinfection and disinfectants, as well as chapters on the bacteriology of sewage, shellfish, meat, soil, air, milk, and water. The book can be recommended as a model of its kind.

La Kinésithérapie de Guerre. La Mobilisation méthodique, la Massothérapie, la Mécanothérapie, la Rééducation. Par Le Docteur P. KOUINDJY, Chargé du Service de Rééducation et de Massage à la clinique Charcot de la Salpêtrière, Aide-major de 2me classe, Médecin traitant au Centre de Physiothérapie d'Arts et de Métiers, V. G. 18. Paris: A. Maloine & Fils, 1916. Pp. 388.

A great deal has been written lately about the treatment of those wounded in battle. The present volume is the author's contribution to the surgery of war. In it are discussed passive movement, massage, mechanotherapy, and reeducation. Each of these procedures is fully explained, the methods of application are shown, and the limitations laid down; at the same time the book contains adequate illustrations. The author has had an unusually large experience in this branch of medical science, and much of what he writes is appropriate to civil surgery as well as to military surgery.

A Manual of Gynecology and Pelvic Surgery. For Students and Practitioners. By ROLAND E. SKEEL, A. M., M. S., M. D., Associate Clinical Professor of Gynecology, Medical School of Western Reserve University; Visiting Surgeon and Gynecologist to St. Luke's Hospital, Cleveland, etc. With Two Hundred and Eighty-nine Illustrations. Philadelphia: P. Blakiston Sons' Co., 1916. Pp. xiv-680. (Price, $3.)

This volume, of handy size, contains a fairly complete account of the diseases of women. Special emphasis is laid upon diagnosis and treatment. The author begins the volume with chapters on anatomy, physiology, and symptomatology and diagnosis; he then discusses diseases and injuries of the vulva; injuries to the perineum; diseases and injuries of the vagina, of the cervix, of the uterine body; uterine displacements; diseases of the tubes; operations upon the uterus and its ligaments; extrauterine gestation; diseases of the ovaries; pelvic cellulitis and peritonitis; congenital anomalies; sterility, gonorrhea, the treatment of menstrual disorders; gynecological therapeutics; diseases closely related to or associated with gynecological lesions; gynecological surgery; and postoperative complications and sequelæ. Particularly useful chapters are those dealing with symptomatology and diagnosis, gynecological therapeutics, and postoperative complications. To each chapter the author has appended a list of references which will serve as a good working bibliography. We suggest that, in a future edition, these references be arranged alphabetically. The size of the book, the size of the type, and the character of the illustrations are all that can be desired. The proof reading has been sadly neglected and the printers seem to have no uniform method of spelling. On one page we find three variations of the spelling of alkaloids, viz., *strychnine, strychnia,* and *atropin; hemostasis* and *hæmostasis* occur on the same page; *hematoma* and *hæmatoma* are found, also *hematoccle* and *hæmatocele;* "spirochete pallida," "locus minoris resistensia," "the constrictor radices clitorides," "the rugarum anterior," "pruritis vulvæ," "one of the tubal fimbria," "maculæ cerulæ," "scybalæ," are some of the flaws which we have detected on our way through the volume.

Preliminary Clinical History. Designed by J. MADISON TAYLOR, A. B., M. D.

This history blank of four pages is designed to be filled out by the patient or the family and covers family and personal history. This scheme has been followed with great success by insurance companies and fraternal orders, and it not only saves considerable time in examination and history taking, but it also brings out many points in the history which might otherwise be overlooked. A section is devoted to the teeth, which are playing more and more an important part in modern medicine.

Interclinical Notes

We have often longed for some high literary authority to cast his eye over our fearful nomenclature, and at last we have found the man. Sir Arthur Quiller-Couch, King Edward VII Professor of English Literature at Cambridge University, tells a most satisfying story. The hybrid which Sir Arthur unearthed made so profound an impression upon him that he keeps referring to it throughout his remarkable book (*On the Art of Writing.* New York: G. P. Putnam's Sons), which is made up of a course of lectures delivered at the University. Hark to his first impression:

It was a work on pathology. I found myself engaged in following the antics of certain bacilli generically described as "antibodies." I do not accuse the author (who seemed to be a learned man) of having invented this abominable term; apparently it passed current among physiologists and he had accepted it for honest coin. I

found it, later on, in Webster's invaluable dictionary: Etymology, "body" (yours or mine), "anti," up against it; compound, "antibody," a noxious microbe.

Now I do not doubt the creature thus named to be a poisonous little wretch. Those who know him may even agree that no word is too bad for him. But I am not thinking of *him*. I am thinking of *us;* and I say that for our own self respect, while we retain any sense of intellectual pedigree, "antibody" is no word to throw even at a bacillus. The man who eats peas with a knife can at least claim a historical throwback to the days when forks had two prongs and the spoons had been removed with the soup. But "antibody" has no such respectable derivation. It is, in fact, a barbarism, and a mongrel at that. The man who uses it debases the currency of learning; and I suggest to you that it is one of the many functions of a great University to maintain the standard of that currency, to guard the *jus et norma loquendi,* to protect us from such hasty fellows or, rather, to suppeditate them in their haste.

* * *

It was by the merest accident that the work on pathology fell into Sir Arthur's hands; and it is most unlikely that he will pursue his reading along such lines. In fact, we doubt if he could read very far just because of the frequent barbarisms. Every one knows how the beautiful lines of Shakespeare sound in the mouth of a bad actor; a similar phenomenon occurs when the purest scientific truth is conveyed in wretched English. The suggestion of the late Achilles Rose was an excellent one, namely, that when a medical discoverer required a new term, he should apply to the University of Athens, describing his wants. The university in question would gladly furnish the neologism, based on impeccable Greek and ready for the necessary modifications when translated into other languages.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 2, 1916:

Foster, A. D., Surgeon. Granted eleven days' leave of absence from June 24, 1916, on account of sickness.

Hommon, H. B., Sanitary Chemist. Directed to proceed to Luray, Va., and such places on the Ohio River watershed as may be necessary in connection with studies of industrial wastes.

Kearny, R. A., Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

Kempf, G. A., Assistant Surgeon. Directed to report to Chairman of Board of Examiners at Bureau, July 31, 1916, for examination to determine his fitness for promotion to the grade of passed assistant surgeon.

Kerr, J. W., Assistant Surgeon General. Directed to proceed to New York for conference relative to investigation of poliomyelitis.

Knight, C. P., Passed Assistant Surgeon. Relieved at Marine Hospital, Stapleton, N. Y., and take charge of the Pensacola Quarantine Station.

Lavinder, C. H., Surgeon. Directed to proceed when necessary and instruct officers under his orders to proceed to adjoining and to New England States to investigate outbreaks of poliomyelitis.

McCoy, G. W., Surgeon. Directed to proceed to New York for conference with officers, collection of material, and planning details of laboratory work in connection with investigation of poliomyelitis.

Treadway, W. L., Assistant Surgeon. Directed to proceed to certain places in the State of Colorado, for the purpose of making a mental examination of the inmates of four institutions for minors.

Weldon, L. O., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

Boards Convened.

Board of medical officers reconvened at the Bureau, Monday, July 31, 1916, to examine Assistant Surgeon G. A. Kempf, to determine his fitness for promotion to the grade of Passed Assistant Surgeon. Detail of the board: Assistant Surgeon General W. C. Rucker, chairman; Surgeon E. A. Sweet, member; Passed Assistant Surgeon J. R. Hurley, Recorder.

Board of medical officers convened at the Marine Hospital, Detroit, Mich., at the call of the chairman, for the re-examination of an alien. Detail for the board: Senior Surgeon H. W. Austin, chairman; Surgeon H. W. Wickes, member; Acting Assistant Surgeon K. L. Weber, Recorder.

Births, Marriages, and Deaths

Married.

Anthony-Curtis.—In Springfield, Mass., on Monday, July 31st, Dr. Jeremiah C. Anthony and Miss Anna L. Curtis.

Died.

Briddon.—In New York, on Monday, July 31st, Dr. Charles Kelly Briddon, aged ninety years.

Cox.—In New York, on Wednesday, July 26th, Dr. Rowland Cox, Jr., of Paterson, N. J., aged forty-five years.

Crawford.—In Milford, Ind., on Wednesday, July 26th, Dr. George S. Crawford.

Detzweller.—In Goliad, Tex., on Saturday, July 22nd, Dr. Joseph Detzweller, aged seventy-two years.

Ellison.—In Kirkwood, Del., on Tuesday, July 25th, Dr. L. Frank Ellison, aged seventy-five years.

Erwin.—In Oak Grove, Mich., on Sunday, July 16th, Dr. William H. Erwin, aged sixty-five years.

Fraser.—In Presque Isle, Me., on Sunday, July 23rd, Dr. Louis Hanley Fraser, aged thirty-seven years.

Frost.—In Montreal, Canada, on Tuesday, July 25th, Dr. Henry Cooledge Frost, of Buffalo, N. Y., aged sixty-six years.

Griebel.—In Indianapolis, Ind., on Thursday, July 27th, Dr. Herman Griebel, aged thirty-one years.

Kelly.—In Fall River, Mass., on Friday, July 28th, Dr. Michael Kelly, aged sixty years.

Kenefick.—In Lawrence, Mass., on Sunday, July 30th, Dr. Thomas Kenefick, aged fifty-six years.

Lewis.—In San Diego, Cal., on Wednesday, July 12th, Dr. Alvah Lewis, of Salt Lake City, Utah.

McHugh.—In Chicago, Ill., on Monday, July 24th, Dr. M. George McHugh, aged thirty-five years.

McLain.—In West Chester, Pa., on Friday, July 21st, Dr. James L. McLain, aged seventy years.

McMullin.—In Philadelphia, Pa., on Saturday, July 29th, Dr. Andrew McMullin, aged sixty-two years.

Pattison.—In Plain Hill, Conn., on Wednesday, July 26th, Dr. Jacob Pattison, aged fifty-eight years.

Phillips.—In Evanston, Ill., on Monday, July 24th, Dr. William A. Phillips, aged fifty-five years.

Rauchfuss.—In New York, on Monday, July 31st, Dr. George Rauchfuss, aged fifty years.

Rodgers.—In Sterrett's Gap, Pa., on Monday, July 24th, Dr. Amos R. Rodgers, aged fifty-five years.

Roof.—In Stamford, Conn., on Friday, July 28th, Dr. Russell H. Roof, of New York, aged sixty-three years.

Shaffer.—In Creamridge, N. J., on Sunday, July 30th, Dr. George W. Shaffer, aged sixty-three years.

Shehan.—In Superior, Wis., on Friday, July 28th, Dr. Lyman B. Shehan, aged sixty-one years.

Slough.—In Emaus, Pa., on Sunday, July 30th, Dr. William C. J. Slough, aged seventy years.

Stone.—In Pigeon Cove, Mass., on Friday, July 28th, Dr. George A. Stone, aged fifty-two years.

Tartar.—In Wytheville, Va., on Saturday, July 15th, Dr. Herman G. Tartar, of Chilhowie, Va., aged thirty-one years.

Wheeler.—In Pittsfield, Mass., on Tuesday, July 25th, Dr. James H. Wheeler, aged seventy-one years.

Wilson.—In Los Angeles, Cal., on Thursday, July 20th, Dr. Andrew P. Wilson, aged forty years.

Wolff.—In New York, on Monday, July 24th, Dr. Benjamin Wolff, aged forty-two years.

Woodbury.—In Groveland, Mass., on Wednesday, July 19th, Dr. Louis Augustus Woodbury, aged seventy-two years.

Woodman.—In Washington, D. C., on Friday, July 28th, Dr. Francis J. Woodman, aged sixty-five years.

Yingling.—In Huntington, Ind., on Monday, July 17th, Dr. Daniel Yingling, aged seventy-six years.

THE TREATMENT OF ACUTE POLIOMYELITIS.

BY S. J. MELTZER, M. D., LL. D.,
New York.

(From the Department of Physiology and Pharmacology of the Rockefeller Institute for Medical Research.)

Acute infantile paralysis is an extremely serious disease. Including even the abortive cases, apparently not more than fifty per cent. of those afflicted recover completely. In the other fifty per cent. the disease either terminates fatally or leaves the patient in a variable degree of invalidism. Considering the seriousness of the prognosis, the status of the treatment of this disease is very discouraging. Diet, purgation, fresh air, sunlight, and rest are the remedies in vogue; they are not to be neglected, but they ought not to impress us with the idea that we are really doing therapeutic work. As to treatment by drugs, Flexner (1) says: "The only drug which has shown any useful degree of activity is hexamethylenamine, which is itself germicidal. . . . But experiments on monkeys have shown this chemical to be effective only very early in the course of the inoculation and only in a part of the animals treated." Theoretically, there stands against its use the fact that hexamethylenamine is active only in an acid medium; while the tissues and the fluid in the spinal canal have an alkaline reaction. From a practical point of view the statement of Fraser (2) deserves to be mentioned. He treated (at the Rockefeller Hospital) twenty-two cases by oral administration of hexamethylenamine. Doses of 0.3 gm. three or four times a day were given to children of two years. "In two instances hematuria developed that ceased as soon as the urotropin was discontinued." "In no instance did this treatment appear to cut short the acute stage, and in no instance was there evidence of more satisfactory or more rapid recovery in the paralyzed parts." This quotation is given, because hexamethylenamine is employed by a number of physicians in the present epidemic, including physicians of hospitals under the control of the department of health. Netter (3) attempted to control the acute stage by subdural injections of serum from recovered patients. Regarding this treatment, Flexner has to say: "Use of this method has been made in a few instances in France, where the blood serum derived from persons who had recovered from infantile paralysis has been injected into the spinal membranes of persons who have just become paralyzed. The results are said to be promising. Unfortunately, the quantity of the human immune serum is very limited, and no other animals than monkeys seem capable of yielding an immune serum, and the monkey is not a practicable animal from which to obtain supplies." According to newspaper statements, this method is now being tested at the Willard Parker Hospital.

Sophian (4) tested the value of intraspinal injections of horse serum in these cases; it seems to him that it exerts a favorable influence. He also tested in a few cases the injection of serum from patients convalescent from infantile paralysis. Of this he says "the results were certainly no better than in the normal horse serum."

For several years I was interested in the treatment of acute poliomyelitis from several points of view. At the special meeting of the New York Academy of Medicine, July 31, 1916, devoted to a discussion of infantile paralysis, I wished to bring forward three definite therapeutic suggestions; but the time allotted to me was "five minutes or less." I chose to devote the greatest part of this short time to a discussion of the use of adrenaline; but obviously I could do very little justice, even to this measure. In the present paper I wish to discuss my suggestions of the treatment of poliomyelitis from a general point of view and at greater length. Those who are open minded will then see for themselves whether my views deserve scientific consideration and my suggestions an honest and unbiased trial.

I shall begin with the next, chronologically the first incident. Several years ago, I was testing the value of my apparatus for intrapharyngeal insufflation (5) on animals with respiratory paralysis. For this purpose I asked Dr. Paul F. Clark, who was then studying experimental poliomyelitis, to let me have a monkey dying from that disease. The first animal brought to my laboratory was undoubtedly in a dying condition. It was completely paralyzed, there were no respiratory movements of thorax and abdomen, none of the concomitant respiratory movements; deep cyanosis existed, the mouth was wide open and the lower jaw hanging down, and there was no lid or corneal reflex whatsoever; but the heart was still beating. I immediately pulled out the tongue, introduced the pharyngeal tube, and started working the bellows and the respiratory

valve. In a short time the cyanosis disappeared, lid reflex and consciousness returned, and the animal was biting the pharyngeal tube. When the tube was removed for a while, no thoracic or diaphragmatic movements appeared; but strong asphyctic contractions of the sternocleidomastoid muscles, the *alæ naris,* and the risorius muscles set in, and cyanosis and unconsciousness developed rapidly. When the tube was reinserted, all these symptoms disappeared and the animal returned to the condition it was in before the tube was removed. It was evident from these observations that the development of asphyxia and the subsequent apparent death of the animal was due to a paralysis of the origin of the phrenic nerves and brachial plexus; *the asphyctic contractions of the accessory muscles of respiration proved that at that stage the respiratory centre was still intact.*

The observation of the further course of this and of another animal in a similar state under prolonged artificial respiration proved that *after several hours the respiratory centre also became paralyzed;* when the tube was then removed, no asphyctic contraction of the accessory muscles of respiration set in; the animal simply became gradually unconscious and strongly cyanotic. But even at this stage, when the animal had artificial respiration, deglutition could be induced and the circulation seemed to have remained intact. A few hours later, however, the circulation began to fail, and the animal, though under continuous artificial respiration, finally died.

These observations demonstrated clearly that the ascending paralysis in poliomyelitis strikes first the origins of the brachial plaxus and the phrenic nerves, and the subsequent asphyxia leads to death in a few minutes. Under the administration of efficient artificial respiration, the animals were resuscitated. We then had a chance to observe the extension of the paralysis, first to the respiratory centre, then to the centre of deglutition which is situated just above the respiratory centre, and, finally, to the vasomotor centre, which is situated still higher and which brought about finally the unavoidable death of animals which received a fatal dose of the virus.

On the basis of these observations I arrived at the general conclusion that in cases of poliomyelitis with *ascending* paralysis, death is due to a respiratory paralysis from an involvement of the origins of the chief respiratory nerves, *while in cases of encephalitic poliomyelitis the vasomotor centre may be the first vital point which becomes paralyzed,* and death is due primarily to a rapid sinking of the blood pressure.

These observations led naturally to the question whether efficient artificial respiration was of therapeutic value in any cases of acute poliomyelitis. We have seen that we could resuscitate the asphyctic animals by means of artificial respiration. It is true that these animals finally died from an extension of the paralysis to the vital centres of the medulla, but we know that in many cases of poliomyelitis the progress of the paralysis is arrested. In such animals artificial respiration could indeed maintain life for a long time. But would such a temporary resuscitation, lasting never so long, be of any final value? If the involvement of the origins of the chief respiratory nerves means real destruction of the corresponding tissues, the condition would be hopeless; the destroyed tissue could never regenerate and life could be maintained only by an indefinite administration of artificial respiration, which is obviously unthinkable. But here I was reminded of a subject in which I was interested in previous years, and that is "the difference between the inflammatory focus and the inflammatory area (*Entzündungsherd und Entzündungshof*)." In an inflammation we have to distinguish between the centre which represents the main inflammatory focus and the surrounding area consisting of zones of cellular infiltration, active hyperemia, and edema. In the centre the original tissue may be destroyed, and when a healing process takes place, it is accomplished by filling up the gap with connective tissue. In the central nervous system such a healing is obviously of no avail. On the other hand, the tissues occupied by the peripheral zones of the inflammatory area, especially those of edema and active hyperemia, may be cleared up with comparative rapidity and returned to normal again. Now the question arose: Does the involvement of the origins of the main respiratory nerves in infantile paralysis consist necessarily in a destruction of the corresponding tissue? Or, can the paralysis in its first stage be brought about merely by the peripheral zones of the inflammation? It is certainly admissible to assume that edema alone, by the virtue of the pressure which it exerts upon the nerve tissue, is capable of producing paresis and even paralysis of the corresponding nerves. If we now assume that in some cases the actual focus of inflammation came to a standstill at a segment of the cord *below the origin* of the chief inspiratory nerves, and that the paralysis of these nerves has been accomplished by the peripheral zones of the inflammation, we may well conceive that prolonged efficient artificial respiration may save life indeed, because the inflammatory condition of these parts is reversible, and it may completely disappear within a comparatively short period.

The earlier pathological studies in poliomyelitis were made in chronic cases of the disease, and the lesions described consisted indeed chiefly of atrophic scars found in the anterior horns of the cord. Since the acute stage of poliomyelitis has been recognized, the pathology of this stage presents another aspect. I shall refer here briefly to the descriptions of Flexner and Lewis (6), of their findings in experimental poliomyelitis in monkeys, and to the lucid monograph of Peabody, Draper, and Dochez (7), based upon their pathological studies of human cases of acute poliomyelitis at the Rockefeller Hospital. Flexner and Lewis say: "Definite lesions of the white matter were not made out, while it is common to find the gray matter altered. The chief lesions consisted of an edema (excessive moisture of the surface), diffuse vivid injection of the bloodvessels, and punctiform or larger (pinhead) hemorrhages." "The lesions . . . tend to be most marked in regions of the spinal cord corresponding with the paralyzed groups of muscles." "The lesions of the medulla, when present, resemble those of the spinal cord. The congestion, however, is more apparent than the hemorrhages." Peabody, Draper, and Do-

chez say (p. 19): "The brain and cord, on section, have a moist, translucent, edematous appearance, and the gray matter of the cord is often swollen so that it projects above the level of the white matter." "These three facts, cellular exudate, hemorrhage, and edema, . . . may perhaps be regarded as the primary reaction of the nervous system to the virus of poliomyelitis." ". . . *the damaging effects can be assumed to result in part from the direct pressure on the nerve cells of hemorrhages, edema, and exudate.* There is also the additional factor of anemia following the constriction of the bloodvessels by the same mechanism." All this was observed at the autopsies. It is possible that, while the victim is still alive and the circulation active, hyperemia and edema are much more extensive than after the heart has stopped beating for some time. That would explain the following statement of these authors: "It is noteworthy, however," they say, "that it is often extremely difficult to reconcile the clinical symptoms which are referable to pontine lesions with the actual autopsy finding. *Cases which have shown bulbar paralysis in life may fail to show adequate anatomical lesions to account for death,* and other cases which have given clinical evidence of spinal involvement may show changes only through the pons and medulla." Apparently some processes may go on during life which disappear as soon as the circulation stops.

From the foregoing it is evident that some of the serious symptoms, those which may even lead to a fatal termination, are due only to edema and other reversible conditions. If, then, the effects of these dangerous but reversible causes could be by some means kept for a time in abeyance, life, at least in some cases, might be saved.

It is therefore a well founded assumption *that there are some patients with acute poliomyelitis with impending respiratory paralysis, the life of whom could be saved by the application of an efficient method of artificial respiration sustained for some time.* Fraser (8) says that in his cases "artificial respiration has been attempted when the respiratory musculature failed rapidly, but in all cases the heart failed before any return of power in the respiratory muscles appeared." The artificial respiration referred to was probably carried out by the Sylvester method. I have tested this method on animals paralyzed by curare (9), and found that twelve minutes was the longest time that this mode of respiration was sufficient to keep the heart beating. With our method of artificial respiration by intrapharyngeal insufflation, the circulation of such animals could be kept up indefinitely (10). That is what I meant when, in my remarks before the Academy of Medicine, I advised to "administer artificial respiration by means of our apparatus for pharyngeal insufflation as soon as the patient shows a degree of unconsciousness and respiratory insufficiency; it is an easy and reliable procedure." While there may be only a few victims who will thus be saved, the attempt should be made in all cases. We do not deal with experimental investigations. *In the practice of medicine we ought to give the benefit of the doubt to our patients, be the chance for success never so small.*

In the foregoing it has been shown that the primary appearance of respiratory paralysis in ascending cases is probably due to the presence of edema and other reversible pathological phenomena in the corresponding segment of the cord. The spontaneous reversion of this phenomena, however, begins only after the chief inflammatory focus has ceased progressing. When that focus starts a regressive process, the edema and other pathological products of the peripheral zone become gradually absorbed. The process of absorption, however, may be very slow, and the lengthy pressure upon the origin of the nerves by these products may, in many instances, lead to a greater or lesser degree of permanent atrophy of the corresponding nerve tissue. It is therefore evident, that if we could find a means by which the edema and other reversible processes of the peripheral zone could be kept down at will continually, or at least very frequently for long periods, even while the inflammatory process of the primary focus was still active, the nerve tissues subjected to the action of the peripheral zone would derive definite benefit. Now, some thirteen years ago, we found that adrenaline is such a reliable remedy (11). In studying the difference of the influence of the sympathetic nerves and of the sympathetic ganglia upon inflammation, we found that we could distinguish these differences best, when the inflammatory area was abolished and the inflammation reduced to its chief focus. This was strikingly accomplished by the injection of adrenaline into the neighborhood of the inflamed part. After a subcutaneous injection of adrenaline into the inflamed ear of a rabbit, the swollen, hot, and red ear soon became thin, cool, and pale in its entire extent, except for a small area in the centre of the inflammation which contained the paralyzed vessels of the inflammatory focus. This effect lasted for some time. Furthermore, in experiments by Doctor Auer and myself on the effects of adrenaline upon blood pressure, it was found that when it was injected into the spinal canal of monkeys, the blood pressure rose slowly, reached its maximum, which was considerable, in the course of half an hour, and often more than an hour passed before it returned to its original level. On the basis of these experiments it seemed to me highly probable that in acute poliomyelitis an intraspinal injection of adrenaline would produce on the peripheral zones around the chief inflammatory foci a prolonged effect of the same character as was observed on the inflamed rabbit's ear. I have therefore induced Doctor Clark, who was then working under Doctor Flexner on experimental poliomyelitis in monkeys, to try the effects of intraspinal injection of adrenaline on these animals. The experiments were carried out under very unfavorable conditions, as the following quotations from Doctor Clark's (11) paper show: "The virus employed *is one that invariably causes a fatal ascending paralysis* or a rapidly fatal paralysis of respiratory centres in the medulla." "The animals selected were *such as were already extensively paralyzed or were moribund* and would have survived only a short time longer." Nevertheless, striking successes were obtained, as may be seen from the following abbreviated protocol B:

February 20, 1912. Animal moribund; breathing feeble and shallow; little tonus in arms and legs, semi-conscious. At 10 a. m., 1.5 c. c. of one to 1,000 epinephrine injected subdurally. No immediate effect. At 10.30 a. m., consciousness had returned and respirations were accelerated. The animal ate part of a banana offered. At 10.45 a. m., respirations deeper. At 11 a. m., marked increase in the tonus of arms and legs; some voluntary motion. . . . At 1 p. m., voluntary movements greater. At 3 p. m., marked improvement; respiration about normal. The animal took food eagerly. At 4 p. m., the tonus in the arms was diminishing; animal still bright. At 4.30 p. m., four c. c. of one to 2,000 epinephrine injected. Animal not seen until 9 a. m. next day, the 21st. On that day, as well as on the 22nd, no injections given.

February 23d. Animal growing weaker and appeared less bright. At 12 m., one c. c. of one to 1,000 epinephrine injected. No marked improvement.

February 24th. Monkey manifested a severe diarrhea during the night; weaker and less tonus in arms and neck. At 12.30 p. m., two c. c. of one to 2,000 epinephrine injected subdurally. At 7 p. m., animal weaker; diarrhea continued.

February 25th. The animal gradually failed and died in the morning.

A moribund animal which received a fatal dose of the virus and which, according to Clark's own opinion, "would have survived only a short time longer," improved after a single injection of 1.5 c. c. of adrenaline, the improvement extending to consciousness, respiration, and paralysis of all extremities; and that animal lived five days longer, although for two consecutive intervening days it received no adrenaline.

It must be evident to every one who is trained in experimentation, that in these few experiments the real value of adrenaline in poliomyelitis received no fair test. The virus employed was invariably fatal; the injections began only when the animal was already moribund; the animal was observed only between 9 a. m. and 5 p. m.; and for two consecutive days had no injections at all; nevertheless, the monkey improved in a striking way and its life was prolonged for five days.

Having conceived this line of experimentation and seeing the striking results in spite of the unsatisfactory execution of the experiments; and being for many decades deeply interested in a critical but broadminded treatment of the sick, could I have acted differently than urgently to recommend a test of the value of adrenaline in the treatment of infantile paralysis in the present epidemic? But having in mind the first principle in therapeutics, which is not to do harm to the patient, I advised that "in human infantile paralysis the injection should be begun with a dose of only 0.5 c. c. of a one in 1,000 solution of epinephrine until more is learned about the effects." But we have learned since from practical experience that much larger doses can be administered without harm to the patient. Furthermore, I discovered that this treatment had already been tried several years ago on human beings. This was done at the Rockefeller Hospital, in 1913, and it was Clark's experiments which gave the stimulus to this therapeutic attempt. I was at that time in Europe and had no knowledge of this fact until I recently read Fraser's (2) article. I shall give here the results in Fraser's own words: "In eight cases in which the *paralysis was rapidly developing and in which there was* EXTREME RESPIRATORY INVOLVEMENT, this line of treatment was tried. The largest dose was three c. c. of a one to 1,000 solution injected along with an equal volume of saline and washed in with one to two c. c. more of saline, but, as a rule, doses of one c. c. or 1.5 c. c. were used." "The dose was repeated in from three to six hours, and the rise of blood pressure was noted. In three cases three doses were given. In one case, twitchings of the limbs came on a few minutes after each dose, in addition to the rise of blood pressure. *In two cases it was thought that the respirations were easier and the diaphragm action better after the injections,* but such improvement was slight and transitory. Of the eight cases, *five ended fatally,* but it is impossible to say in the *three cases that ended favorably* that the arrest of progress in the paralysis was due to the injections." Here we see again that *this line of treatment was tried only in advanced cases in which the paralysis was developing rapidly and in which there was extreme respiratory involvement.* The usual prognosis in such cases would be that all eight would have a fatal termination. The recovery of three out of eight, that is, about thirty-eight per cent., is therefore most satisfactory evidence in favor of the usefulness of the treatment of infantile paralysis by adrenaline; and even in cases in which an "extreme respiratory involvement" has already set in, this treatment is not too late. I wish to point out especially that the experimental and clinical data cited here were obtained several years ago in the laboratories and the hospital of the Rockefeller Institute.[1]

Since my remarks at the meeting of the Academy of Medicine were made, one hospital (N. Y. Throat, Nose and Lung Hospital) has treated with admirable thoroughness all their cases (over seventy, I understand) of infantile paralysis with intraspinal injections of adrenaline.[2] I do not intend to discuss the favorable results which the physicians of the hospital believe they have obtained. I shall leave it to them to publish their scientific report which, as I understand, is under preparation. But one fact I wish to point out, which stands out clearly and indisputably: All the children sick with infantile paralysis in that hospital received two c. c. of adrenaline every six hours (which was carried out day and night with zeal and great care by the house surgeon, Dr. P. A. Lewis), and not in a single instance was any untoward symptom observed which could be ascribed to the adrenaline injections. The important therapeutic requirement that a medicine or any method of treatment should do no harm, has thus been overcome and settled. I am frequently receiving information from private sources of the treatment of infantile paralysis with adrenaline by private physicians. So far all seem to have obtained favorable results.[3]

[1] Soon after my remarks on the use of adrenaline in infantile paralysis became known through the daily press, persons connected with the department of health assumed an inimical attitude to this treatment for reasons best known to them. One physician of that department went so far as to say that "there is nothing in it and he is sure that the Rockefeller Institute agrees with him." I do not know to whom he refers. But I am sure that nobody who is connected with the Institute is in possession of facts different from those quoted above, which undoubtedly speak in favor of the use of adrenaline in infantile paralysis.

[2] Since July 29th, the department of health is not sending any more cases to that institution as I understand, on account of a technical regulation.

[3] The following incident in a fatal case is instructive. A young man of twenty years, a patient of Dr. J. Gardner Smith, was sick

My own judgment, however, is not influenced by such reports. I shall quote here what I said in the *Medical Record* for July 22 (p. 160): "Will adrenaline accomplish a real cure? Any one who is trained in experimental and clinical criticism can readily see that this question cannot be answered for some time to come." The report of one case, or of several, of a cure or a failure cannot decide this question, especially in a disease in which the mortality is comparatively low. I have given in detail my physiological, logical, and experimental reasons for my belief that the use of adrenaline in acute poliomyelitis is very rational. The clinical experience brought sufficient evidence that it can do no harm.[4] I therefore honestly believe that it is the duty of every physician who has to treat acute cases of poliomyelitis to give it an honest and unbiased trial.[5]

Furthermore, it seems to me that adrenaline ought to be given even in cases which are treated by the administration of serum from patients convalescent from poliomyelitis. The serum, if efficient, may be capable of arresting only the progress of the inflammatory focus; but the absorption of the edema is a slow process and the prolonged pressure upon the nervous tissues surrounding the focus may cause the area of the residual paralysis to remain more extensive; on the other hand, the simultaneous administration of adrenaline may assist in hastening the removal of the edema and thus be the means of reducing the final size of the residual paralytic area. Scientifically, it may be admitted that the simultaneous use of adrenaline in these cases will complicate the experiment and thus reduce its value. However, *in dealing with human beings we ought to have in mind preeminently the help which we may possibly be able to render to the patient and not look upon the treatment exclusively from an experimental point of view;* we must give the patient the benefit of the doubt. By the way, it is obvious to me that the final conclusions which we shall be in a position to draw from the serum experiments may remain doubtful, at least from a purely scientific point of view.

As can be seen from the foregoing, my advice to use adrenaline in acute poliomyelitis is based upon actual experimental observations of its effect upon inflammatory processes in general. I confess, however, to being guilty of entertaining an accessory hypothesis, according to which adrenaline may indeed exert a specific action upon the virus of poliomyelitis. The hypothesis is, briefly stated, as follows: According to Langley, Elliott, and others, the chromaffine tissues (medulla of adrenals, etc.) are identical with the tissues of the sympathetic ganglia. My hypothesis assumes the possibility that *the adrenals as well as the sympathetic ganglia may be specifically antagonistic to the virus of poliomyelitis.* This assumption is based partly upon the experiments of Flexner, Clark, and Amoss (12). They have examined histologically the lesions present in the intervertebral ganglia, the Gasserian ganglia, and the sympathetic ganglia (solar plexus) of monkeys which died from experimental poliomyelitis. They state that "the severest (lesions) occurred in the intervertebral ganglia, those next in severity, the Gasserian ganglia, while the mildest appear in the abdominal sympathetic ganglia." "The cellular accumulation within the abdominal ganglia (solar plexus) are least marked and so constantly perivascular, that infection by way of the blood is indicated. The nerve cells exhibit the slightest lesions of all the ganglia studied." The adrenals, so far as I know, were not studied. According to the authors cited, the sympathetic ganglia showed the greatest resistance to the virus of poliomyelitis. While this fact may be explained merely by the assumption that the sympathetic ganglia have least affinity for the virus, it does not preclude *the other possibility that the nerve tissues of sympathetic ganglia are antagonistic to the virus.* That is, when an emulsion of sympathetic ganglia was added to an emulsion of the spinal cord, the infectivity of the latter was greatly reduced. Obviously, my assumption is merely an hypothesis; but an hypotheesis which is readily accessible to experimental test.

TECHNIC OF ADMINISTRATION.

In the following I shall try to formulate the advice which I wish to give with reference to the use of adrenaline in poliomyelitis—at least at the present stage of our knowledge of the subject. As soon as the diagnosis for poliomyelitis is established, two c. c. of one in 1,000 adrenaline should be injected every four to six hours. Before the first injection is given, a fairly large quantity of spinal fluid should be withdrawn, the quantity being in proportion to the pressure prevailing in the spinal canal. The subsequent injections should be made without regard to the presence or absence of spinal fluid. Unless the pressure appears to be very high, I advise that in advanced cases not much of spinal fluid be withdrawn, because at this stage the spinal fluid may already contain some useful antibodies.. All injections should be washed in with two c. c. of a normal salt solution. but if no spinal fluid is present the adrenaline should be washed in with at least five or six c. c. of salt solution; in the presence of fluid in the spinal canal the adrenaline will more readily spread all over the cord. In serious cases the quantity of adrenaline administered may be as much as three c. c. to each injection. In cases in which the encephalitic symptoms are predominant, however, greater care should be exercised with reference to the quantity of the injected adrenaline; it should be used in inverse proportion to the exciting effect which the injections may produce. In previous experiments I found that adrenaline is often destroyed

for several days. During this period he suffered from severe headaches and vomited occasionally; the eye muscles and the muscles of the neck were paretic; both anterior extremities were nearly completely paralyzed and the involvement of the respiratory muscles was pronounced. It was a severe case of an encephalic type complicated by bulbar spinal phenomena. The lower extremities were in a state of spastic paralysis. The prognosis of the case was obviously very bad. From 5 p. m. on the day I heard of the case the patient received about every four hours two to three c. c. adrenaline intraspinally. Next morning I learned that the respiration was undoubtedly improved and that the patient could move his arms. The patient died in the evening, apparently under some sort of convulsive manifestations. Doctor Smith will probably publish the case in greater detail. What I wish to bring out here is the fact that in this hopeless case the adrenaline unquestionably reduced the paralysis perceptibly, although to no avail as to the final results.

[4] In encephalitic cases with great excitability it seems that greater care ought to be exercised in selecting the proper doses.

[5] Reports coming from hospitals and physicians who have manifested an antagonistic attitude from the start will obviously have to be taken with a grain of salt. Besides, only such reports could be taken into consideration which come from men who have given evidence of possessing ability for critical observation in the science of medicine.

when mixed with human spinal fluid (13). I prefer therefore that the injections should be given oftener, at least every four hours when possible. The injections should be continued until four to five days after all paralysis has disappeared, or at least until no further reduction in the extent of the paralysis has taken place.

In my remarks at the meeting of the Academy of Medicine (14) I suggested further that in treating acute poliomyelitis, oxygen should be administered "under pressure in a respiratory rhythm by an apparatus which I have recently devised and used on human beings in several instances." I shall not describe this apparatus in detail. It consists essentially of a hollow tongue depresser which is connected with "the respiratory valve." The latter is connected with a large rubber bag, which in turn is to be connected with an oxygen tank. The tongue piece should be introduced into the mouth only so deep as not to produce gagging. When the ring of the respiratory valve is turned to the left and the oxygen is turned on, oxygen accumulates in the bag. When the ring is now turned to the right, oxygen enters under pressure into the mouth. When the ring is turned rhythmically, coincidentally with the respirations of the manipulator, the patient receives oxygen under pressure in a respiratory rhythm. As a rule the patient adapts his own respiration to this rhythm. In several cases with deep cyanosis I saw the cyanotic face of the patient turn in less than one minute to a pink color. There is no doubt that under these manipulations the oxygen of the blood is greatly enriched. Since this manipulation causes the patient no annoyance whatever, I advise employment of this method very early in the paralysis in order to assist in overcoming respiratory difficulties. Furthermore, according to Hill, the administration of oxygen increases the tonicity of the heart muscles as well as of the skeletal muscles.

I have another reason for recommending the use of this method, however, in acute poliomyelitis. Since there can be no doubt that by employing this method the quantity of the oxygen of the blood plasma is for a time considerably increased, a part of this oxygen must escape into the lymph within the tissues. Vernon and Hill hold that oxygen is "five times as soluble in fat as in water at one atmosphere" (15). We have thus reason to assume that the lipoids of the nervous system may be the ones which will receive the greatest part of the oxygen of the plasma surcharged by administration of the oxygen under pressure. Now according to Flexner and Noguchi (16), the infective cause of poliomyelitis is an *anaerobic* organism. If what has been already stated is true, we have good reason to assume that the administration of oxygen under pressure may bring a greater amount of oxygen to the nerve tissue and thus cause greater or less hindrance to the free development of the virus of poliomyelitis. This is what I meant when I said at the Academy that "it may even act specifically on the virus of poliomyelitis."

I therefore recommend the administration of oxygen under pressure by the above mentioned apparatus, for twenty or thirty minutes at a time, every two or three hours. This procedure, in the first place, can certainly do no harm; it is further likely to aid in overcoming respiratory difficulties, and, finally, it may even be a specific factor in combating the development of the virus of poliomyelitis.

AUTOTHERAPY IN POLIOMYELITIS.

By Charles H. Duncan, M. D.,
New York.

In autotherapy the physician treats the patient with unmodified toxic substances elaborated within the latter's body, by the action of the infectious agent on the body tissues, against which the tissues react in a curative manner.

In view of our apparent helplessness in the presence of an epidemic of poliomyelitis, I suggest that the autotherapeutic method of treatment be given a fair trial. It is especially worthy of consideration since cerebrospinal meningitis, another toxic neuritis, appears to respond readily to this treatment.

During the spring of 1910, Dr. C. C. Howard, of New York, cured a case of cerebrospinal meningitis by tapping the spinal canal and injecting intramuscularly the spinal fluid thus obtained. Recognizing this treatment as autotherapeutic, he asked Dr. H. C. Sloat, then of New York, to read a paper, The Relation of Autotherapy to Homeopathy, before the Homeopathic Medical Society of the State of New York, at its annual meeting held in Albany, February 22, 1911. During the discussion that followed, Doctor Howard reported the case of cerebrospinal meningitis mentioned above, and Dr. George F. Laidlaw, of New York, stated that he had cured many cases of cerebrospinal meningitis by this autotherapeutic method. Time and space forbid giving more than that part of the discussion which relates to the injection of the spinal fluid:

Dr. C. C. Howard stated that last spring (1910) a patient with cerebrospinal menengitis entered the Metropolitan Hospital. The man was an Italian laborer, about thirty-nine years of age, and in a state in which one would expect a speedy death. He was cyanosed, his pulse was erratic, he was bathed in a cold sweat, rigidity was marked, and there was loss of all reflexes. The case approached so near death, that the speaker decided to see what results would follow injection of the spinal fluid under the skin. He made a spinal puncture, drew off quite a large amount of fluid, and injected some of it into the muscles of the back. In the course of three or four hours the temperature fell from 105° to 102° F. Four injections were given in a similar manner. The man had absolutely nothing re-

maining as the result of the attack and was perfectly well when he left the hospital.

Dr. George F. Laidlaw, referring to Doctor Howard's case of meningitis, thought he was the grandfather of this treatment, Doctor Sloat the father, and Doctor Howard their lineal successor. He thought he was the first to draw the spinal fluid in a meningitis case and inject it under the skin. Within the past year he had been puncturing the spinal canal quite liberally. He had been surprised at the number of apparent cases that had a sterile spinal fluid, in which prompt improvement might follow its injection under the skin. One striking case he had about a year ago; another he saw in Scranton, in November, 1910; another in Flower Hospital. Others he had seen about New York at different places. All the symptoms were those of meningitis; rise of temperature, stupor, flexor spasms of the knee, retraction of the neck, etc. In all cases he punctured the spinal canal and drew off a fluid free from pus and bacteria. Those patients seen at different stages of the disorder injected with about ten drops of spinal fluid, within ten hours were so much better that he was forced to conclude that the injection of the spinal fluid had some influence on the improvement. The bacterial cases he had had the misfortune to see late in the disease, ended fatally. Doctor Howard's patient was the only one of this type that he had seen recover, and he attributed this to the adoption of the treatment early in the disease.

It seems altogether probable that if the spinal fluid was passed through a Duncan autotherapeutic apparatus before injection the results would be more certain, in some instances at least.

It is altogether probable that in advanced stages of this neuritis, as in cerebrospinal meningitis, the spinal fluid may contain, in addition to the etiological factor, pyogenic microorganisms which, of course, would be removed by the filter.

This is an autotherapeutic cure, pure and simple, and is freely acknowledged as such by Doctor Laidlaw, Doctor Sloat, and Doctor Howard. If it had not been specifically pointed out that autotherapy is especially applicable in poliomyelitis, it must have suggested itself over and over again to those who do their own thinking, that autotherapy is particularly applicable to this infection. Being a toxic neuritis, with the evidence before us of the effectiveness of autotherapy in cerebrospinal meningitis and other toxic neuritides, it would be only a slight mental effort to conclude that autotherapy might also be applicable in this form of neuritis.

While one swallow does not make a summer, neither does one case ordinarily mean anything, still a straw tells the way the wind blows. The writer has had only one case to study; for the prevention of epidemic necessitated sending it to the city hospital.

Case. Patient, male, aged two and a half years, was taken sick, July 22, 1916. The case was not seen until the twenty-fourth. There was vomiting, stupor, and a temperature of 102° F.; slept with his eyes open and rolled up. There was marked twitching of the muscles of the legs and arms. On the twenty-fifth, there was a partial left sided facial paralysis and partial paralysis of both legs. On the evening of that day the spinal canal was punctured and about ten c. c. of fluid withdrawn, and one c. c. injected hypodermically. Within twelve hours the stupor disappeared and the temperature fell to 99° F. He was sent to the hospital, where 0.5 c. c. injection of spinal fluid was given. At the present writing, August 7th, temperature and pulse are normal.

Since the onset of the paralysis is so sudden and the condition is often not diagnosticated till partial paralysis is manifest, it is altogether probable that the value of this autotherapeutic treatment lies in aborting the disease if treated sufficiently early, and stopping the progress of the paralysis when the treatment is not instituted too late. The partial paralysis without doubt will in many instances be overcome in the course of time. The writer suggests that tests be made in treating tetanus and other toxic neuritides, by the autotherapeutic method.

Since the foregoing was written, the author has had the opportunity to study upward of a dozen cases of poliomyelitis which appeared to confirm the favorable prognosis in patients treated autotherapeutically.

THE CONTROL OF EPIDEMICS.

What Should Be Done in Invasions Like the Present One of Infantile Paralysis,

By Jacolyn Manning, M. D.,
Saratoga Springs, N. Y.

The report presented by the council of eminent pathologists and bacteriologists recently assembled in New York city, recommending methods for controlling the present and future epidemics of poliomyelitis, omitted a point of great value in determining the exact degree of invasion of the plague; a point, which investigated, will throw much light on unrecognized cases of the disease, and which uninvestigated allows an enormous and constant leak through the wall of protection quarantine in any community.

When a plague has obtained a foothold in any community, the cause of every death occurring in that community should be scientifically established. A competent pathologist and diagnostician should investigate the cause of death, and the contributory cause of death should be stated on each death certificate, during the period the plague is active. Where there is the slightest doubt of the cause of death, a post mortem examination should be made of the central nervous system, brain, midbrain, and spinal cord. This examination should be both gross and microscopical, and taken together with animal inoculation of the post mortem material, constitutes the only method known to medical science today for determining with absolute accuracy whether or not any person, adult or child, dying during epidemic invasion, has been a victim of poliomyelitis.

The list of diseases terminating in sudden death which may simulate poliomyelitis is quite extensive; including, in very young infants, gastroenteritis, bronchopneumonia, measles, and diphtheria; and in adults, ptomaine poisoning, lockjaw, cerebral apoplexy, and heat stroke.

Many instances are known by epidemiologists of mistaken death certificates having been rendered during epidemics, where a subsequent case of frank paralysis in some other member of the family, gave sufficient indication that the death had been due to the epidemic virus.

The fact that a post mortem examination constituted the only absolute method of arriving at the cause of death, was indelibly impressed on the writer's mind during three years' attendance on weekly autopsies conducted by Ludwig Hektoen in the morgue amphitheatre of Cook County Hospital, Chicago. As we all know by experience, the attend-

ing physician and consultant, by elaborate methods, often arrive at a correct diagnosis of an illness terminating in death, and often they do not; but the trained pathologist conducting an autopsy, reads the cause of death from the tissues open before him, as plainly as the reader reads this print.

As a dairyman once said to the writer, he never believed that one of his sleek cows could have tuberculosis, until he attended the post mortem examination of some cattle among his neighbors' equally fine herds, and saw the huge foci of tuberculosis in caseous lungs and suppurating kidneys, and the glandular inflammation of the bags of the cows dissected by the veterinary pathologist of Wisconsin Agricultural College. This man then submitted his cows to tuberculin test; thirty-five were found to be infected and were slaughtered: the remaining herd was removed to a new barn, and no more cases developed. Without the convincing evidence of a post mortem examination, the dairyman's cows and all subsequent additions to it would have contracted tuberculosis from daily contact with unknown carriers.

How much more important it is to apply extreme prophylactic measures when the activities and existence of the children of our nation are threatened. A missed diagnosis and faulty death certificate in a fatal case of epidemic poliomyelitis endangers the community more than a case of frank paralysis. The innocent family, servants, and friends, all may come in contact with the body and its late environment, while a public funeral opens a wide channel for further communication of the contagion.

A point of less but unquestioned value in handling an epidemic, which kills by the thousand, and cripples when it does not kill, is the communal necessity for the *interdiction* of all *public funerals in* any city during the progress of an epidemic.

For the week ending August 5, 1916, the New York city board of health reported 188 deaths from diarrheal disease of children under five years of age. It would be interesting, and might prove instructive, to hold post mortem examinations for one week, with microscopic examination of the central nervous system, of all fatal cases where the death certificate stated gastroenteritis to be the cause of death.

44 Walton Street.

AN EVALUATION OF PARAPHRENIA.*

By Edward A. Strecker, M. D.,
Philadelphia,
Assistant Physician, Pennsylvania Hospital for the Insane.

The tendency of modern psychiatry to insist on a more rigid distinction between true paranoia and the merely paranoid psychoses has had at least two important results. In the first place it has established clearer concepts relative to these two conditions. It has further served to widen appreciably the border line territory between dementia præcox —the psychosis in which paranoid ideas are most common—and true paranoia where they reach their fullest development. If we are prepared to accept the Kraepelinian valuation, we will think of paranoia in the sense of a "mental twist" rather than as a frank psychosis; we will view it as the maladjustment of a brain inherently biased toward a faulty manner of thinking and finally as a condition maintaining a permanent delusional level and not tending to progress to definite end states as do those chronic mental disturbances which are considered endogenous in their origin. Such an hypothesis at once excludes a vast number of progressive insanities, which in view of their symptomatology and end states, are obviously unable to conform to a condition said to be "the unfolding of a psychopathic personality in contact with the conditions of life." On the other hand, if we establish a criterion for dementia præcox, which implies in its course some dementia of affect-life and some disturbance in the domain of the will, we will again be obliged to withdraw a number of cases from the schizophrenic group. Certain investigators actuated partly by the clinical necessity of finding a place for the paranoid psychoses which could not be forced into the preexisting nosology, and in part, too, by the peculiarity of their onset, course, and terminal status, have attempted to gather them together under new classifications. Perhaps the most notable effort in this direction is Kraepelin's presentation of the paraphrenias.

KRAEPELIN'S CONCEPTION.

Kraepelin (1) separated from the vast mass of chronic paranoid material a group of patients who were remarkable for the late and insidious onset and gradual development of their psychoses; the presence of adequate emotional reaction and will function; absence of dementia in the ordinary sense, and above all the striking retention of personality. These cases stood out so sharply that he was unable to find a niche for them, even on the outskirts of the præcox group. He was therefore led to announce a new classification—paraphrenia — for which he asserts a more or less true clinical entity. Individual differences suggested a subdivision into the systematic, the expansive, the confabulatory, and finally the less clearly recognized fantastic form.

Briefly, paraphrenia systematica is a chronic paranoid psychosis of late onset and extremely gradual course, in which persecutory ideas are subjected to an exhaustive mental consideration; later, grandiose delusions are engrafted and the system thus evolved is maintained without perceptible shrinkage for many years. Hallucinations, usually of hearing, appear only after the delusional condition has become well established. The dwindling of psychic life, the disappearance of personality, the loss of emotional values, catatonic phenomena, and in short all those manifestations which we regard as indicative of the *dementia* in præcox, are strikingly absent.

Expansive paraphrenia presents the gradual construction of an elaborate system of grandiose delusions, with prevailing elevated effect and mild excitement. Undoubtedly many of these cases would parallel "chronic mania," a favored diagnosis ten and even five years ago. The same factors which drew the boundary line between systematic paraphrenia and dementia præcox are also present here, though they are often less clear.

*Read at the meeting of the Philadelphia Psychiatric Society, College of Physicians and Surgeons, Philadelphia, Pa., May 12, 1916. The author is indebted to Dr. Earl D. Bond for his assistance in the preparation of this paper.

The third division, confabulatory paraphrenia, is quite rare. Kraepelin has seen only twelve cases in thirty-five years. It is marked by highly elaborated and detailed falsifications of memory forming the foundation for a psychotic structure consisting largely of related delusions of persecution and grandeur.

The final variety, the fantastic form, is deserving of but little consideration as a separate disease group. Kraepelin himself recognizes its close kinship to dementia præcox. It comprises cases which show a profuse development of highly fantastic, disassociated, and ever changing delusional conceptions.

THE LITERATURE.

While Kraepelin's attempt to enlarge the classification of mental diseases has excited practically no comment and apparently awakened but little interest in this country, it has on the other hand been productive of an extensive literature from European authorities. Not the least fruitful result of the general discussion has been a more intensive study of all that interesting and rather indefinite group of psychoses in which the paranoid trend is most prominent and characteristic.

Bleuler (2), who thinks of dementia præcox or schizophrenia more and more as an abstract psychopathological mechanism, and less as a clear cut disease form, feels that paraphrenia is merely a highly unusual expression of paranoid dementia præcox. Of course, the observer who views mental irregularities through psychological lenses, and who rather shrinks from any definite and final delimitation, and the one with the vision of the clinician who is naturally seeking to classify symptomatically, can find no common ground on which to reconcile their differences. Bleuler's premises relative to schizophrenia are so broad that practically every chronic paranoid condition must be included at some point in its course. His three so called primary symptoms, namely, some alteration in the processes of thought; some disproportion of emotional reaction; and some withdrawal from the environment are capable of numerous interpretations and elaborations. Hallucinations and delusions which are usually regarded as such important clinical landmarks, are here set aside as secondary symptoms, merely incidental and not necessary for diagnosis.

Krambach (3) made an intensive study of fifty unselected chronic paranoid cases in the hospital at Dösen, and found that about ten per cent. might be regarded as paraphrenia. Subjected to the criterion of Bleuler, practically all of these fell by the wayside, chiefly on the basis of inadequacy of thought and emotional reaction. To escape the præcox label Bleuler would have his chronic paranoids display, not only what might be termed "logical affectivity," that is, the emotional status of the patient must be in keeping with the delusional content, but there must further be "logical and well ordered thought processes." Therefore, to merit any consideration as distinct from the schizophrenic group, the ideas which form the content of a psychosis must be consistent with the individual false premises which are its foundation stones. This is systematization carried to the highest possible degree, a conception which seems rather more theoretical than real. If it exists at all, it will only be in the occasional rare case of paranoia vera, and paraphrenia, as defined by Kraepelin, can never survive such a severe test. Careful analysis will always uncover a thought ramification, which in relation to the central delusional vein is either elaborated too much or is perhaps too constricted, or which may even remain abortive.

Krambach reached a conservative conclusion from the study of his cases. He feels that the relative integrity of the affect and will is certainly highly suggestive and deserves further investigation, but that the close relationship in many respects to dementia præcox is too important to be ignored. His verdict as to paraphrenia is that it is a protracted and very unusual expression of paranoid schizophrenia in which the will and emotional fields escape the brunt of the dementing process.

Kleist's (4) exhaustive study of a rather small group of cases, nine women and one man, led him to differ materially from both the "disease process" theory of Kraepelin, and the psychogenetic interpretation of Bleuler. This is merely illustrative of the fact that no matter how scientific may be the attitude in which an investigator approaches a problem, the result is found to be influenced by the personal equation. The age of onset, well beyond the fifth decade, the period of involution, was evidently the important determinative factor in the formation of Kleist's etiological theory along the lines of retrogressive changes in the sexual organs, the circulatory system, and the body in general. He suggests organic brain changes, physiological rather than destructive in their nature. By adding to these a psychopathic personality (fairly well substantiated in the anamneses of his cases), he arrived at the result of a paranoid symptomcomplex of the involutional time, which he designated involutional paranoia.

Albrecht (5), in reviewing the functional psychoses of the involutional age, was able to isolate a group of twenty-four, two thirds of whom were women, which practically parallels paraphrenia and involutional paranoia. He recognizes the kinship to the chronic paranoid deterioration of Kraepelin, but feels that his cases showed even less tendency to progress. They are designated the "presenile paraphrenias."

Moravesik (6) of Buda-Pesth, makes the basic distinction between paranoia and paranoid on the ground of reaction to environment. The former observes, ponders over, and weighs carefully the happenings in the world about him. Slowly he weaves them into his psychotic life. Finally he reacts, and the response is always entirely in accord with the false conception. On the other hand, the paranoid shows an affective reaction almost immediately, but it is lacking both in depth and completeness. He is inclined to ally paraphrenia to dementia præcox.

Hosslin (7) likewise regards harmony between behavior and mental conceptions as essential for paraphrenia, and questions the validity of this diagnosis with the possible exception of the confabulatory form.

Neither Pfersdorff (8) nor Gregor (9) can bring himself to accept the Kraepelinian viewpoint.

Most of the authors who object to the paraphre-

nic classification have retained their chronic paranoid cases in the dementia præcox group. Stransky (10), on the other hand, would include them with paranoia on the basis of richness of delusional content and completeness of systematization.

Hübner (11), in reviewing the chronic cases at Bonn, found an interesting group in which in the course of years there ensued a gradual and partial correction of the delusional system. The intelligence was well preserved and the personality intact. Therefore, the reduction in psychotic content could not be ascribed to a dementia in the ordinary sense of the word. On the other hand, there was in no sense a recovery, for the original groundwork of distrust, seclusiveness, and peculiarity was still very evident.

AN ANALYSIS OF FOURTEEN CHRONIC PARANOID CONDITIONS.

At the present time there are more than one hundred cases in the hospital which have been diagnosed as dementia præcox. An overwhelming majority of this number, about eighty-five per cent., have in the course of years deteriorated to a common level of profound dementia. Whatever individuality they once presented has been blotted out by the permanent stagnation of every mental faculty. Indeed were it not for the histories it would at times be impossible to piece out even the nature of the original psychosis from the mental wreckage remaining after a lapse of thirty and sometimes forty years. About fifteen per cent. of the entire number, however, possess certain points of interest. Even a rather superficial survey of the mental status of this smaller group will at once show that its claim to separation from the majority, lies chiefly in the fact that the integrity of personality has in these patients been better able to withstand the disorganizing shock of the psychosis. We are inclined in some sense to view them first as individuals and only later as schizophrenics. The average age of these fourteen patients is fifty-two years, the youngest being thirty-three and the oldest sixty-seven; the duration of the mental symptoms ranges between one year and forty-six years and averages seventeen and one half. In about fifty per cent. there is a history of mental disease in the ancestry, two being particularly notable in view of the prominent and far reaching effect of the hereditary taint; were it possible to complete early histories, the percentage would probably be materially increased. Generally speaking, they were not normal children; seclusive tendencies were most frequently noted and there was a fairly large proportion of intellectual precociousness. An analysis of what in some sense might be termed the "basic mental faculties," namely, attention and memory, reveals little deviation from the normal. Unless the question happened by chance to strike against one of the pillars of the psychotic structure, the answers were usually without error. Orientation was practically undisturbed. In the emotional field we find the first and perhaps most important determinative factor in placing these cases within the schizophrenic group. More or less complete apathy, the dementia of affect life, is present in eight of the fourteen cases; severe blunting can be demonstrated in five, and in only a single instance is there apparently an adequate emotional tone. In the domain of the will there are even more general and more significant disturbances. In ten of the patients the expression of defective will inhibition is to be seen in such symptoms as mutism, resistiveness, violent scolding or screaming spells, refusal of food, negativism, and catatonic manifestations of various kinds. Hallucinosis is present in more than two thirds of the cases and in more than one half it involves both the auditory and the visual fields. A large percentage of our group had been variously diagnosed as mania, chronic mania, and allied to manic depressive, classifications conditioned perhaps as much by the uncertain character of the symptomatology in the early stages as by the restricted methods of study. The delusional structure, beside being essentially paranoid, possesses at least two other points of interest. In more than one half of the cases there has been a progressive contraction, both as to the quantity and quality of the delusional content, until at the present time there remain only a few scattered threads of a once richly woven fabric. This seems to be of considerable importance, for it may well be regarded as almost conclusive proof of a dementia, even though such deterioration may be difficult or even impossible to establish by any series of formal tests. The same association of mental functions which in the normal mind gives rise to a conception, must also operate in the insane, even though its method of working is an abnormal one. If therefore a false idea or a system of false ideas, which was once complete, connected, and detailed, begins gradually to lose its cohesiveness and sequence without essential correction, we are justified in inferring a decline of those mental elements which gave it birth. The general reaction to the delusional content is also, in some sense, a measure of the amount of mental loss, which has been sustained. If the response throughout is adequate and logical, it would indeed be difficult to establish deterioration, no matter how unbalanced the individual might happen to be. If, on the other hand, there is a marked disproportion between belief and behavior, which increases from year to year, there is additional proof that we are dealing with some type of dementing process. In all but one, or possibly two of the selected group, there is a significant gap between the delusion and the behavior response of the patient who holds it.

TWO CASES OF PARAPHRENIA.

It will thus be seen that a group of psychoses which at first glance appeared to offer considerable variation from the usual dementia præcox type, falls readily into line when subjected to a more critical analysis, particularly in respect to the affect and the will. A single case deserves further consideration as illustrative of so called paraphrenia.

Case 1. M. R., admitted in 1908 at the age of forty-five years, had been living in a very secluded way for three years; denying admission to all visitors and securing provisions by summoning a messenger boy and dropping written instructions with sufficient money, from one of the windows. It is said that for two years she did not leave her house. Apprehensive and suspicious. Wrote many defamatory letters. Imagined herself very wealthy and possessed of great landed estates in England. It was necessary to force an entrance into the house in order to bring her to the hospital.

At first there was apparently a free expression of delusions, both persecutory and grandiose. She called on the police to arrest the President of the United States and other foes who were accusing her of immoral conduct; King Edward was trying to obtain possession of her property; Emperor William was her particular friend; she was only twenty-nine years old, of foreign birth, and had no connections in this country. Later, she became much more chary of her spoken productions. Hallucinations of hearing were noted shortly after admission. Apparently they increased during the first four years and then gradually became less prominent. There was no definite evidence of either affect or will abnormality and her conduct in general was a consistent protest against detention in the hospital.

At the present time the patient is highly suspicious of a direct question and will not cooperate in any examination, either physical or mental. She cares for her person and room, in spite of an unusually large ovarian cyst, which has greatly reduced her strength and lessened her activity. Attention and memory, both recent and remote, are quite good. She is perfectly oriented. She is interested in daily happenings; keeps in touch with the world's events through the columns of the newspaper; and is able to discuss intelligently what she reads. Her affective life is in fairly good alignment with her delusional beliefs. To her enemies, who are legion, she shows scant courtesy; to her friends she is pleasant and affable; often she jokes in a natural manner. Her reactions to the ordinary incidents of daily life, when not affected by her delusional conceptions, are not much overdrawn. It is difficult to decide whether or not hallucinations are present. Her letters contain reports of numerous imaginary conversations, always of a derogatory nature. There is a rich delusional structure. Men and women prominent in political and social circles; officers of the hospital, the nurses, and even the chance visitor, are all drawn into the conspiracy against her; the connecting link consisting of innumerable ideas of reference and possibly intentional falsifications. She speaks of the crowned heads of Europe and their courts in terms of closest intimacy. The ultimate conclusion, the *pièce de résistance* of her delusions, is concealed even in her written productions; occasionally there are veiled hints as to her real identity. Probably her touch with the actual world is too real and her understanding too shrewd, to let her commit the error of divulging all her beliefs at the present time. The system of persecutory and grandiose delusions has not undergone any contraction with the passing of years; on the contrary, it continues to expand and flow into new channels.

The following selected productions will give some idea of the patient's fancied intimacy with the crowned heads of Europe and others who at present occupy a prominent position in the public eye. Of course, falsification cannot be excluded and is probably an important factor in the patient's psychic life.

I see by the paper that the King of Greece has decided not to go in with the Allies.

Do you know the King, Miss R?

No—but I do know the Queen—she is the Kaiser's sister and she certainly wears the "pants." She can twist her husband around her little finger. I well remember the last time I was home in England—I was at the Lord Mayor's reception in London and the Queen of Greece was there raising money for a German hospital; I never liked the Germans much and I said to an old duchess with whom I had been discussing the Queen's activities—I'll never give one red cent toward a German hospital. Shortly afterward the Queen came up—ah—she's a smooth talker—and what do you think—in less than ten minutes she had my promise for several thousand dollars. (Lord Kitchener's name was mentioned.)

You know Kitchener, do you not, Miss R?

Oh, yes indeed—I know him very well. I well remember talking with him at one of Queen Victoria's receptions. He is fine looking, and many titled ladies had their eyes on the General, but he would scarcely look at them. He is a woman hater and always avoids affairs when they are present. He told me it was his custom when he got any invitation to go out to ask the question: Will there be ladies present? And only when a negative reply was received would he accept. Queen Victoria tried a dozen times to marry him off and I remember one of the last stories she told in my presence was this: Kitchener, why don't you marry—is there no one you love? There is, your Majesty—one whom I deeply love and adore. Ah—said the Queen, scenting a romance, and who is the fortunate lady? Your Majesty, replied the General. The Queen never tried again to make a match for Kitchener.

Things don't look any better over in Europe?

Not a bit—I see no change—no improvement. Now the question is—nobody seems to know the cause of the war— Nobody practically knows what the cause of it is— Whether Emperor William wants to be boss—I can't get head or tail of it.

We don't hear much about the King of Greece now, do we?

No.

What has happened there?

It was in the paper about three months, or four months ago, where he had to go under an operation—it didn't state what the operation was for. You see—Sophia—she's the youngest sister of Emperor William—she is said to be the handsomest princess of all Europe— She's a beautiful woman— Not a picture really gives her justice.

You said you met her?

I know her, but I'll tell you—she's so polished— Oh, my—her manners—she's like the Kaiser— He would just kill you with politeness—he's very polite. She's a beautiful blonde—beautiful blue eyes—the most magnificent golden hair— She's the best looking one in the family. You take the Kaiser—he's what you would call a handsome man— He's just as straight as an arrow.

Is there anything in the story of him having difficulty with his arm?

Yes—it's his left arm— Notice in his pictures you will always find his hand inside his coat— Ever notice that? Never leaves the arm down— That arm is shorter than the right arm— It might be about a finger length shorter.

Enough to make him sensitive about it?

He's more sensitive about it than what anybody else would be. Now if he wouldn't do those things— This is what gets me—sticking his hand inside his coat and inside his trouser pocket draws people's attention to it.

Was it his sister that got in on you for that donation?

Yes—Sophie— Nobody else could get in on me for a donation.

She got around you pretty well, didn't she?

Oh, yes— She's a lovely person.

The quite voluminous correspondence of the patient forms a very interesting chapter, of her psychosis. A number of communications are addressed to department stores and contain orders for large quantities of carefully described articles with explicit directions for delivery. In others, real estate agents are instructed to buy various properties which have been advertised in the daily press. Of a more intimate nature are the letters to her attorney. They keep him informed of the progress of the conspiracy; direct him just how to proceed, instruct him as to the individuals who are to be subjected to legal action and the damages to be sued for. In these epistles she reports the overheard conversations of her persecutors; describing just how she

has been annoyed and closing with a demand for immediate release. In another series she addresses the representative of Great Britain in terms of polite superiority, advising him to move cautiously and "make no rash promises." Often there is an order for goods enclosed, which are "to be charged to the British Government and taken out of my income."

Her communications are clearly written, but there is a tendency to monotony of phraseology, misspelling, insufficient punctuation, and a lack of connection between the individual phrases of a sentence, which suggests beginning intellectual deterioration.

I include a few excerpts from the patient's letters. The following was her reaction to the visit of a consulting surgeon.

There was a man came here on Sunday, March 7, 1915, and gave his name as Dr. G. He lives at 1618 S——— Street, this city, and he stated that he was asked to come here by Dr. S——— to examine my abdomen and he demanded me to lie down on the bed and I will not lie down on the bed as there is no *law* to compel me to do the same. He also said that he would fix me and that I could not have any law suit. And he did not obtain his end this Dr. S——— told him he did not know he was coming and if he did he would have given me a dose and when I came to it would be all over. I want you to put these two men under arrest as soon as you receive this letter.

He told me that you were a friend of his and that he had removed your appendix two years ago, and if this was so, I would have seen this in the daily paper and when Dr. G——— told me this I knew he was telling me a bare face *lie* and you are to handle him roughly and also hand in an injunction on everything he owns and when he is up against me he is not up against a fool and this same Dr. G. is going to be made pay the penalty for the same. What is more I will not stand the insults of the low born subjects and not resent the same and I will make trouble for the U. S. A. all right.

She often refers in her letters to the yacht *Niagara*. "I am very much worried about my yacht, *Niagara*, and I leased it to some Americans from Chicago for two years' cruise of the world and I have not heard from them and as their time is nearly up and they might be detained in the war zone."

From a letter to a former nurse, now visiting Ireland: "I hope you had no trouble in fishing in the River Bawn on my estate, Gilford Castle, Corner Gilford Station, Portadown, County Down, Ireland."

From a letter to the British Consul: "I have been here six years and five months and I do not propose to stay here and not be well paid for doing the same and which I demand from the U. S. A. thirty-five million dollars."

Following the staff meeting at which her case was considered: "I want to know just what right this Dr. N——— had to question me and try and pry into my private affairs and you are to try to find what his object was. I just stood and looked at them and made no answer to any of them. Also find out the names of the other men and who or whom sent or told them to come here and do the same."

From a letter to her attorney:

I heard that some one got into my house at 1441 S. B———- Street, this city, and destroyed my things, broke all the glass in the china closet and also the china and the glass, etc., and tore the paper off in the dining room and sitting room, etc. For this loss this man will be made to pay five million dollars for the same and I do not say that this man B——— B——— mayor of Philadelphia, did the same himself, but he paid some one to do the work for him and he will be held responsible for the same and will surely be made to pay the *Penalty*.

From a letter to her attorney: X——— Y——— Z——— is the name of a nurse and appears many times in the patient's communications:

This old slut, X. Y. Z., is going around among the patients telling them I have nothing and now I would like to know who or whom gave her the authority to do the same and what is more I do not know that I had hired her as my bookkeeper or private secretary and if I wanted one I would not hire a common old slut like this X. Y. Z. or any one belonging to her.

On my way to dinner I heard this dirty common old slut, X. Y. Z., telling an attendant some of her lies about me and whose name is a Miss A. B. and I would like to know just what she said and I would like if you would send a detective to find out just what old slut, X. Y. Z. had said.

From a letter to her attorney: The advertisement mentioned actually did appear in the paper and is her former residence:

Enclosed you will find where there is an add in the Sunday *Inquirer*, where my house at 1441 South B——— Street, this city has rooms to rent and as I am just tired out about this thing. In addition to the five million which the Mayor of Philadelphia will have to pay me, as there are sixteen words in this *add*, he can pay five hundred dollars a word, which will make it a total of eight thousand dollars additional I do not say he put same in said paper himself, but he hired someone to do the same for him and he will be made to pay the *Penalty*.

From a letter of protest to her attorney: The date of admission is correctely stated:

I am here just six years and eleven months today, June 2nd, 1915, when I was brought in here I was only to stay one half hour, and its the d——— longest half hour I ever saw and you can state in the letter to the Mayor of Philadelphia that he will be made to *pay* the penalty to date, June 2, 1915. This Dr. O. N. or M. said to an attendant by the name of Miss M. N., from Sunbury, Pa. that I was a devil let loose out of *Hell*, and he also said on the same day to the man who had charge of the electric lights some kind of a remark about me and he told Dr. O. N. or M. if he said the same about a sister of his, he would be put in jail for life, in the Penitentiary where he belongs.

P. S. The new title that I have now is that old slut X. Y. Z. called me an *English Devil* and when I get at her I will make her jump sky high, and I would not want anyone to be saying about me what is said about old slut, X. Y. Z. that she was a notorious thief and liar, and how she will lie, and then lie to get out of the same.

From a letter to her attorney: Similar complaints frequently appear:

This J. S. told some patient that she was going to stretch some heavy cord across the hall to throw me and I want her arrested at once as she is not fit to run at large, as this is not the first time, or the second time she has made this threat, and now I want to know who or whom she is and all about her.

From a letter to her attorney: A prominent financier is drawn into the conspiracy:

I heard this on Christmas day, December 25, 1915, that this man, Edward S. had gone to Mrs. ——— ——— corner of Eighteenth and W. Streets, where he told her he would pay up all he owed and she said, that he had had seven years to do the same and has not done the same. You are to get habeas corpus for his arrest at once and above all you are not to allow him out of jail on bonds and also you are to run in an injunction on all his money, bonds, stocks, real estate, personal property, horses and carriages, autos, etc., and all the jewelry that he had given that woman he had married, and also the house of 1925 W. Street this city, and also the country house at G. Pa. As he had admitted that he had stolen

the same and do not let up on this man ——— ———, supposed to be president of Z. and Company, S. E. Corner of D. and C. Streets, this city.

From a letter to the British Consul:

Enclosed you will find a list of articles of which I have need and which you are to charge to the English Government and they are to take the same out of my income. You are to make no rash promises of any kind as none will be granted and I will give nothing and neither will I make settlement of any kind and remember I will do all that I said I would do and carry out the same to the last letter.

The incidents related in the following letter are correctly recalled after a lapse of almost seven years:

West Phila. *Nov. 25,* 1915.

Mr. A. P. L. S——— Dear Sir

Would you please take this matter up for me in the Court as I would like to know why I am held in the Penna. Hospital for the Insane at 4401 Market St., West Philadelphia, Pa. for 7 yrs. and 3 months on Dec. 2nd, 1915 as I do not know that I did anything to keep me here and I was put in here by a Special Officer A——— B——— on July 2nd, 1908 and I was taken from my house at 1441 So. B——— St., Phila., Pa. by the same said Mr. B——— and another man whom I did not know his name and they forced an entrance in my house by the use of chisel and by breaking the catch and the lock of the upper and lower sash of the window on the front of my house and as my house has bay windows and the one they forced an entrance was the one that was near the steps and also breaking inside shutter and I was in the 2nd story-front room and was looking over some papers and this Special Officer A——— B——— came up to me and put his hand on my shoulder and he said that he was going to take me to Court and in the place of that I was placed in the Penna. Hospital for the Insane, 4401 Market St., West Phila., Pa. and I have been here ever since and this is why I would like if you would please take the matter up for me to have a hearing in the Court as I would like to know who it was or whom the person or persons that placed me in this Hospital and also for what was the cause for them to do the same and I do not think that I gave any reason why I should be held as a captive? And I hope you will please get me my liberty and so I can pack all my clothes and all that belong to me so I can return to my home at 1441 So. B——— St., Phila., Pa. hoping you will please give this your personal attention and thanking you in advance for the same and hoping to hear from you at your earliest convenience.

Oblige yours truly
(Miss) M——— C——— R———
(My home) 1441 So. B.——— St.
Phila., Pa.
At present time is (Miss) M——— C——— R———
4401 Market St.
West Phila., Pa.

In addition to the possibility of intellectual loss, this case is further separated from paranoia vera by the absence of marked inner psychic tension, the disproportion between many of the individual false concepts and the lack of logic displayed in linking them together; the tendency to overpromptness of affective reaction, which thereby loses something in depth; the hallucinosis, and above all the fact that we are here dealing with a frank psychosis and in no sense with the unfolding of a psychopathic personality.

It is still more distantly removed from dementia præcox, because the affect and the will have remained relatively intact; after a duration of at least eleven years, the patient still possesses her points of contact with the every day world and retains her personality; finally, characteristic dementia has not appeared.

(*To be concluded.*)

A STUDY OF DRUG ACTION.

Fifth Communication,

By Thomas J. Mays, M. D.,
Philadelphia.

MUSIC.

Sound, the basis of music, is a force like heat, light, and electricity, and possesses the fundamental physical properties of motion, action, and reaction, etc., with which the other physical forces are endowed, and is amenable to the same therapeutic laws which obtain among the substances that have been considered in the foregoing pages of this series of papers.[1]

Speaking more specifically, music is a force, the elective action of which is confined to the field of the human emotions. But one distinguished writer presents this subject by asking, "How do we account for the expressiveness of music? Whence comes it that special combinations of notes should have special effects upon our emotions?—that one should give us a feeling of exhilaration, another of melancholy, another of affection, another of reverence? Is it that these special combinations have intrinsic meanings apart from the human constitution?—that a certain number of aerial waves per second, followed by a certain other number, in the nature of things signify grief, while in the reverse order they signify joy? Few will be so irrational as to think this. Is it, then, that the meanings of these special combinations are conventional only?—that we learn their implications, as we do those of words, by observing how others understand them? This is a hypothesis also devoid of evidence. How, then, are musical effects to be explained? If music, taking for its raw material the various modifications of voice which are the physiological results of excited feeling, intensifies, combines, and complicates them; if it exaggerates the loudness, the resonance, the pitch, the intervals, and the variability, which, in virtue of an organic law, are the characteristics of passionate speech—it produces an idealized language of emotion; then its power over us becomes comprehensible."

This theory implies that if music takes for its basis the vocal expressions of excited feeling and exaggerates their loudness, resonance, pitch, etc., it produces an ideal emotional language, but this ideal language gives us no inkling why war, patriotic, drinking, and national songs arouse and electrify human emotion to the highest pitch of ecstasy, while mournful tunes and funeral marches spread a universal feeling of depression. Whence this power? Does it reside in the very fibres and constitution of music? Is it not possible that it is the result of special tone combinations of music itself, and is independent of any exaggeration of the "loudness, the resonances, and the pitch of passionate speech," as is held by the authority herein cited?

It may, indeed, be said that some music is exhilarating because it is written in a major key, and another kind is depressing because it is expressed in a minor key. The real cause for the contrast must, however, be sought further down.

When the sounds of the major chord C, E, and G,

[1] See this Journal, for August 14, November 20, 1915; January 1, March 16, 1916.

for example, are compared with those of the minor chord C, E flat, and G, we find that the small and almost indistinguishable difference in the number of vibrations between E and E flat is responsible for the profound difference of effect between these two combinations, and, as a principle, it illustrates the dissimilar impressions which are produced on human sensibility by major and minor music—the former, being of an agreeable mould, promotes a pleasurable and satisfied feeling, while the latter is the result of incomplete harmony and produces a disagreeable, or only a half satisfied impression.

It must be fully understood, however, that a minor key does not stand for an actual discord, but merely for a jar just sufficient to cause what Professor Helmholtz denominates "dysharmony." In qualifying this peculiar phenomenon, this eminent authority[2] says: "Harmony and dysharmony are distinguished by the undisturbed current of the tones in the former, which are flowing as when produced separately, and by the disturbances created in the latter, in which the tones split up into separate beats. . . . In dysharmony the auditory nerve feels hurt by the beats of incompatible tones. It longs for the pure efflux of the tones into harmony. It hastens toward that harmony for satisfaction and rest."

Moreover, music is a physiological force of great power; it moulds human feeling and conduct, and it is frequently employed, either consciously or unconsciously, with that end in view. The music of a brass band, marching through the streets of a town, sends a thrill through the whole population. Music of this class is indispensable in time of war, to excite the people, and to maintain the discipline and ardor of the soldiers while going into battle, when making long and tiresome marches, to cheer up the wounded and the sick in hospitals, and to relieve the despondency of dreary camp life. Much of our social and domestic life is greatly strengthened and invigorated by music that pertains to home, love, the cradle, parting, to wandering, college, the church, patriotism, and nationalism. So do the waltzes, the polkas, the minuets, the schottisches, etc.

Considered physiologically, it has so far been found that music is an agency that possesses a profound influence on human emotion, and that it exerts a stimulant, as well as a depressant action; and it now remains to be pointed out how these properties may be made available in the field of therapeutics.

Its stimulant action lies within the bounds of the various major keys, which may be said to move in harmony with the normal bodily forces: and its depressant action, while not having an intense antagonism to the normal movement of the bodily forces, nevertheless, sets up a sufficient degree of interference with the latter to occasion a state of mental despondency. In other words, major music is a tonic to the emotions, at least in moderate quantities, and evokes joy, animation, hope, happiness, and courage, and its action may be compared to that of a tonic or stimulant dose of strychnine, or of quinine; while minor music depresses emotional activity, the action of which is analogous to that of a bromide, or of a sleeping potion.

[2] *Harmony in Music*, p. 105.

It is in place here to anticipate an objection which may be made in reference to the foregoing classification of the effects of major and minor music. Why is it, it may be asked, if minor music is likely to subdue and to quiet emotional activity, that most lullabies, which are supposed to soothe restlessness and to promote sleep, are written in major keys? Does it not seem that minor music would be more serviceable in bringing about quietness and repose?

This is an apparent, but not a real, contradiction. For, if it is true that major music possesses a stimulating or a tonic influence, it is not a difficult matter to show how this form of music may serve as a sleep producer in children. Sleeplessness may be due to at least two causes. One, that of a depressed or weakened physical or mental activity of the body, or both, and the other because of mental or nervous excitement; each condition, however, indicating a subnormal mental or nervous state.

In the former trouble, it seems to be preferable to resort to means which tend to tone up and to elevate the underlying depressed and weakened nervous system, and which, as has already been indicated, incline to move in harmony with the natural forces of the body—the class to which major music belongs—rather than to employ depressant agents which interfere or clash with the tendency of the healthy body forces. Moreover, stimulants and tonics are more permanent in their effects, and their administration is also in accord with the common practice of giving a little hot milk, beef tea, a few drops of aromatic spirits of ammonia, or a sip of anise or peppermint tea, for the same purpose, and far preferable to the pernicious custom of flying to the paregoric bottle, or to some popular soothing syrup.

Furthermore, major music, which is assumed to be of an exclusively stimulating nature, is often combined with minor passages in the same composition, and, indeed, in national airs or war songs, the sole object of which is supposed to arouse and to excite human passion. This is another seeming inconsistency, but really the combination is in perfect accord with the main object of this article; for such a feature is frequently introduced, and for the sole purpose of exalting the stimulating and exciting effect of the music as a whole. This is specially obvious in the construction of the *Marsellaise*, probably the most vigorous and intensifying belligerent air ever produced. In this hymn, the eighth and ninth lines are depressed into a minor key, and the immediately succeeding major lines are thrown into such a bold and brilliant relief that the intensity and power of the emotional effects are driven beyond the bounds of description. It is related that when Rouget de Lisle, the composer, gave the first rendition of this song, his audience was thrown into a fit of wildness, which changed into furore when he made the final passage from the minor key to the major refrain: "To arms! to arms! ye brave! ye brave!" etc.

Professor Helmholtz, as already quoted, makes clear the purpose of such combination when he says that when the ear is offended by dysharmony it longs for harmony and rest. Similar effects are brought

about in some lullabies, and in other songs written in major keys, by the employment of one or more minor chords, or by the introduction of a few accidentals.

When we come, then, to make a practical application of music as a therapeutic agent, it may be well to remember that it has already been tested as such in certain forms of insanity and of nervous diseases, and not without success, and it is the writer's belief that, as an agent in the treatment of consumption, it probably has a stronger claim on the scientific attention of the medical profession than many of the remedies which are in use at the present day. Indeed, no system of treatment, in our enlightened knowledge of the physiological pathology of this disease, can afford to ignore the perturbed nervous and mental condition which is an ever present factor, and which is actually demonstrated to belong to that domain of phenomena which are deeply influenced by the agency under consideration.

In considering the form of music most available in the treatment of consumption, it seems probable that by far the larger number of such cases will receive benefit from the various forms of major music. For it is a patent fact that, no matter how cheerful and elated patients of this kind may seem to be, in their lonely moments there is nearly always present an undercurrent feeling of tribulation and of oppression. It is this feature which must be kept uppermost in mind when treating this disease; and, in view of this, it is hardly necessary to add that the interests of such sufferers are best subserved when they are protected, so far as possible, from all mental annoyances, and when placed under the influence of agencies that create an atmosphere of cheerfulness and buoyancy, in which major music does not fail to play an important role.

1829 Spruce Street.

AMERICAN MEDICINE OF THE EIGHTEENTH CENTURY.*

By George Wythe Cook, M. D., LL. D.,
Washington, D. C.

Unlike the moral sciences—which are based on more or less determined principles—medicine as a science has been greatly circumscribed by reason of the small knowledge we have had of the intricate physiological functions of the body, and our no less limited understanding of the pathological changes, as well as dense ignorance as to the causes of these changes, to say nothing of our imperfect understanding of the physiological and therapeutic effect of the so called remedies we are accustomed to use, so that our practice has necessarily been largely empirical. Measured by the light of today, medical men of the eighteenth century—even in the old countries—were groping in the twilight of great uncertainty.

These reflections are not prompted by a censorious spirit, but merely emphasize the difficulty by which the science of medicine, even under the most favorable circumstances, is encompassed. Therefore in undertaking a study of American medicine of the eighteen century we must keep in mind the limitations by which medical men of this country and of that period were circumscribed. We must remember that they lived in a new and sparsely populated country, that they were thousands of miles removed from the centres of civilization, with a broad ocean lying between, which in those days it took weeks to traverse, and when the transit had been accomplished the fountains of medical science from which they could drink were shallow indeed! But they had a thirst for knowledge and many of them sought those springs and imbibed with avidity such knowledge as was to be obtained. They were qualified by preliminary education, too, and it is surprising at what an early age—fifteen years—many of them received their literary degrees. That they were thorough is evidenced by the fact that each one wrote his thesis in Latin and defended the opinions therein expressed in the same language.

There was no medical school in America until after the middle of the eighteenth century. The method of instruction was by a system of apprenticeship which extended over a period of from three to seven years—a most valuable method of instruction, for it brought the student into close contact with his master, enabling him to acquire the latter's methods in the most practical way. Many of these men had been born and educated in Europe before coming to the New World, and their students in turn went to Europe in order to obtain a medical degree. It is not intended to intimate that all practitioners were so well educated, for such was not the case, but in a study of this kind it is only right to give first place to the best.

Considering the sparse population of not more than three hundred thousand at the beginning of the eighteenth century, strung out along the Atlantic seaboard from the rock bound coast of New England to the sunny shores of Georgia, remote from the centres of civilization, we should scarcely expect to find among a pioneer people struggling with the wilderness and battling with savages any who could find time or opportunity for scientific pursuit. Yet there were some who stood as shining lights in science and should be of interest to us as medical men, though they may be overshadowed, in the view of the general public, by the clergy, the statesman, and the soldier.

Perhaps the most interesting and notable event occurring in the medical annals at the beginning of the period with which we are dealing was the acrimonious controversy originating in Boston over the introduction of inoculation for smallpox, the great protagonist of that procedure being the redoutable Cotton Mather, of witchcraft fame, a distinguished politician and divine.

In 1718, Dr. William Douglass, an educated and astute Scotchman, came to Boston, bringing with him among other scientific papers, one written by an Italian named Timoni and communicated by Doctor Woodward, in 1717, to the Royal Society of London, describing the method of inoculation as practised among the Turks. Though not on the best terms with Mather, Douglass gave him among

*Read before the Medical History Club, of Washington, D. C., February 26, 1916.

others this paper on Turkish Inoculation. Smallpox was raging in and about Boston, and Mather was profoundly impressed with the Turkish method of inoculation. He proposed to Douglass that he give the method a trial, but Douglass ridiculed the idea, as did other Boston physicians to whom Mather proposed it. But the resolute old clergyman was not deterred by the rebuffs of the Boston physicians.

There lived in Brookline, contiguous to Boston, Dr. Zabdiel Boylston, whose father, Dr. Thomas Boylston, an Englishman having the degree of M. D. from Oxford, in conjunction with Dr. John Cutter, an eminent physician and surgeon of Boston, directed his education, though it does not appear that he ever received the doctor's degree. Yet he was a distinguished physician and besides was noted for his interest in botany and natural history. To him Mather proposed that he undertake the work. Boylston readily assented and "entered eagerly into the scheme to stamp out the plague." Boylston must have been a man of strong conviction and rare courage, for notwithstanding the violent and threatening opposition of medical men, the clergy, and the laity, the first subject whom he inoculated was his only son, a lad of thirteen years; then two negro servants were likewise inoculated, all of which operations were entirely successful.

The controversy was sharp and stubborn, the opposition being led by Dr. William Douglass, to whom Mather originally proposed that he initiate the procedure, assisted by Dr. Lawrence Dalhonde, a Frenchman, who had a large practice in Boston. Many of the clergy denounced the practice from their pulpits, and the *New England Courant*, a paper edited in part by Benjamin Franklin, was active in opposition. Mather and Boylston and their supporters were persecuted unmercifully. Boylston was assaulted in the streets, attempts were made to burn his house, and bombs were thrown into his and Mather's houses. Notwithstanding this vehement opposition the practice was so successful that it gained steadily, and doctors established private hospitals for the purpose of inoculation.

Hutchinson, quoted by Packard, says: "In the year 1721, and first part of 1722, Doctor Boylston inoculated 247 persons; thirty-nine were inoculated by other persons in Boston and its vicinity. Of this number only six died, and several of those were supposed to have taken the infection before inoculation. In the same period 5,759 took the disease the natural way, of whom 844 died, and many of those who recovered were left with broken constitutions and disfigured countenances."

Mather wielded a tremendous influence with the clergy, and his prestige was no less potential with the laity, so that he rallied his followers—who had at first opposed him—to the side of inoculation. Here was the remarkable circumstance of the clergy advocating science and the faculty opposing it; but the dominating influence was the cool perseverance of Doctor Boylston, who ultimately experienced the pleasure of having his practice endorsed. That arch objector, Dr. William Douglass, recanted, and Benjamin Franklin was converted to a belief in the utility of inoculation. Boylston's triumph was complete. He was invited by Sir Hans Sloan, physician to George I, to come to London to demonstrate his method, which he did successfully. His reward was great. He was made a member of the Royal Society of London, being the first native American to be so honored. He also received a thousand guineas as a gift from the King.

There were many practitioners of the type of Zabdiel Boylston scattered throughout the colonies. They were men who, though they had not acquired the doctor's degree, had nevertheless been trained by skilled physicians and surgeons who had migrated to the Colonies, and who were, as well, educated in the school of experience and well qualified to treat disease according to the light of their day. These men must not be included with the pretenders and charlatans, of whom there were not a few, for they were conscientious and trustworthy practitioners.

There were also many notable medical men of fine attainments in the various Colonies. They came as surgeons to the King's troops, or were those adventurous spirits who came to the new El Dorado in search of fame and fortune. They were principally from the British Isles. As the colonists acquired wealth, those who undertook the practice of medicine were not content with their apprenticeship, but went to Europe in order to increase their knowledge and obtain the coveted medical degree.

It would be profitable to study some of these men individually, were it within the scope of this paper, for some of them were most interesting and attractive. They were acute observers and beside being skillful physicians they were adepts in botany and natural history. They corresponded with the members of the Royal Society and with the great botanist, Linnaeus, who honored some by naming plants after them. Dr. Howard A. Kelly has found material enough to write a most interesting volume about these botanists.

Dr. John Mitchell, who lived in a small village on the Rappahannock River in Virginia, was a Fellow of the Royal Society of London. He was distinguished as a botanist as well as a physician. Among other papers he wrote one giving an account of the yellow fever which prevailed in Virginia in the years 1737, 1741, and 1742. Some years after his death, the paper came into the hands of Benjamin Franklin, who transferred it to Doctor Rush; he published it and acknowledged his indebtedness to it for information enabling him successfully to combat the disease.

Dr. Hezekiah Beardsley, of Connecticut, was the first to describe congenital hypertrophic stenosis of the pylorus in the infant.

Dr. John Lining, of Charleston, S. C., in the year 1740, made careful studies in metabolism from observations upon himself, ascertaining daily his weight each morning and evening, the weight of food taken, and the weight of his urinary and alvine discharges. These investigations were carried on throughout a year and were published in the *Transactions of the Royal Society of London* in 1743.

Dr. William H. Welch in a discussion said: "Many of these frontier doctors were fully the

equals in education of their contemporaries along the Atlantic seaboard; in Boston, New York, Philadelphia, Charleston. Of course in the middle of the eighteenth century Charleston was perhaps the most cultured centre. There is a wonderful group here that has never been presented to us. I have made many appeals to have this done, by some one from that region, if possible."

Beside being physicians they were men of affairs, taking great interest in the wellbeing of their country. A number of them were in the colonial legislatures—several were lieutenant governors (and practically governors) of the colonies, and no fewer than five were members of the Continental Congress, and, as such, signers of the Declaration of Independence. General Warren, who lost his life at the battle of Bunker Hill, was a doctor, as was General Hugh Mercer, of Virginia, who was killed at the battle of Princeton.

Opportunities for the study of practical anatomy were few not only because of popular prejudice, but because in some of the colonies the study was a legal felony. The bodies of executed criminals were sometimes given for the purpose of dissection, but the prejudice was so great even against that practice that one body which had been given the doctors by the authorities of Baltimore was forcibly taken from them by the infuriated populace.

The famous "doctors' mob" that occurred the same year (1788) in New York city was most serious in its results, and gives evidence of the intensity of feeling in the matter. Some doctors and students were dissecting in the New York Hospital building. A boy peeped in at the window. A dare devil student waved an arm of a cadaver at him, which so terrified the boy that he fled crying down the street, and soon an excited multitude had assembled and hearing his gruesome story made a vicious attack on the building. It was now the doctors' and students' time to run, and, pursued by the mob, they sought refuge in the jail. The police were unable to control the situation, and the militia were called out. The mob remaining defiant and aggressive, the militia fired, killing seven of the rioters and wounding many others.

Doctors are expected and required to know all about the human anatomy, but many obstacles are put in their way to prevent their acquiring such knowledge. A number of sporadic efforts were made in the first half of the century to cultivate practical anatomy, but with indifferent success. It was not until about the middle of the century that it made much progress. The bodies of executed criminals were furnished by the authorities for dissection purposes, but the principal supply of material was obtained by "body snatching."

Historians agree that unquestionably the best anatomist and the equal of any surgeon of his day in this country, was William Baynham, a native of Caroline county, Virginia. He received his preliminary education at home, and when twenty years of age was sent to London and entered St. Thomas's Hospital as a student. Here he made the acquaintance of Mr. Else, the professor of anatomy, whose assistant he became. His skill in injecting and preparing anatomical material was declared to be wonderful.

He remained in London four years and returned to his native colony to settle in Essex county, where he had an extensive practice and a wide reputation as a skillful and successful surgeon. Here is an instance of a scholarly man and skilled scientist remaining in a country district remote from the centres of population attaining success and distinction. There were some great doctors in the years gone by, and geniuses are not to be found within the metropolitan districts only.

Midwifery, in the earlier part of the eighteenth century, was practised almost exclusively by women, except that in some difficult case a doctor might be called to give aid, though the practice of obstetrics by men was extremely unpopular. It was said of Doctor Attwood, of New Jersey, he "is remembered as the first Dr. who had the hardihood to proclaim himself as a man midwife: it was deemed a scandal to some delicate ears, and Mrs. Grany Brown, with her fees of two or three dollars, was still deemed the choice of all who thought women should be modest."

Dr. John Moultrie, a Scotchman, who came to Charleston, S. C., in 1733, was perhaps the earliest regular obstetrician of the colonies. He died in 1773, having stood at the head of his profession in that city. It was said of him: "He was especially distinguished for his skill in obstetrics, and his death was regarded as a public calamity. Several of the ladies of Charleston bedewed his grave with tears, and went into mourning on the occasion. The year after his decease was distinguished by the deaths of several women in childbirth. While he lived they thought themselves secure of the best assistance in the power of man or of art, in cases of extremity: In losing him they lost their hopes. Depressing fears sunk their spirits, and in an unusual number of cases produced fatal consequences."

Dr. James Lloyd, a pupil of William Hunter and Smellie, who settled in Boston in 1752, was probably the first medical man in New England to devote himself to the practice of obstetrics.

Dr. William Shippen, Jr., of Philadelphia, was the earliest teacher of obstetrics in this country, his lectures beginning in 1762.

Dr. John V. B. Tennant, of New Jersey, an alumnus of the University of Edinburgh and a Fellow of the Royal Society, was the first professor of obstetrics of the Medical School of New York.

Dr. George Buchanan, of Baltimore, in 1789, delivered a course of lectures on the Diseases of Women and Children and the next year a course on Midwifery. These sporadic efforts were indicative of a desire for further improvement in medical education.

To the physician the hospital is not only a refuge for the sick and wounded, but is an educational means of vast importance. The first general hospital established in the colonies was the Pennsylvania Hospital of Philadelphia, which was organized in 1751, and in February of the next year advertised that it was ready to receive patients. Dr. Thomas Bond, of Maryland, who had settled in Philadelphia, was its chief projector; he was ably and efficiently seconded by Benjamin Franklin.

This hospital was established on a sound and enlightened basis, as is evidenced by the wise and judicious rules adopted by the board of managers.

M. de Warville, who visited the hospital in 1788, wrote: "I have seen the hospitals of France, both at Paris and in the provinces; I know none of them but one at Besançon that can be compared to this at Philadelphia. Every sick and every poor person has his bed well furnished, but without curtains, as it should be. Every room is lighted by windows placed opposite, which introduces plenty of light. . . . The hospital is fine, elegant, and well kept."

Although the Pennsylvania Hospital provided for the care of lunatics, the earliest institution for the special care of the insane was the Eastern Lunatic Asylum, at Williamsburg, Virginia, chartered in 1772 and opened the next year for the reception of patients.

The second hospital to be founded in the colonies was the New York Hospital, chartered in July, 1771. Doctor Fothergill, of London, was one of the incorporators. Before its completion, the building was almost completely destroyed by fire in February, 1775, but it was quickly reconstructed and the Provisional Congress took possession of it for use as a barracks in April, 1776. When the British entered New York city the same year they used the building as barracks for the Hessians. It was not reopened as a hospital until 1791.

That the colonists were interested in education is obvious from the fact of the establishment as early as in the seventeenth century of Harvard College in Massachusetts, and William and Mary College in Virginia. In the eighteenth century many other colleges were founded, but in none of them was there a medical school, until, in 1765, the medical department of the College of Philadelphia was organized.

The two moving spirits in this adventure were Dr. John Morgan and Dr. William Shippen, Jr. Both were Philadelphians, and both were graduates of the medical department of the University of Edinburgh. They were well qualified for the undertaking. The former was appointed professor of theory and practice of medicine and the latter professor of anatomy and surgery. Other professors were added from time to time, including Dr. Adam Kuhn and Dr. Benjamin Rush. Dr. Thomas Bond, who was the founder of the Pennsylvania Hospital, was appointed to give clinical lectures. Three of these were the most conspicuous medical men of the colonies. Two of them, Morgan and Shippen, were surgeons general of the Continental armies, and Rush was surgeon general of the middle department of the Continental army.

Here was laid, and well laid, the foundation of medical education in this country. Students came in at once and in increasing numbers—there being between thirty and forty in attendance in 1775—when the school was interrupted by the Revolution.

The medical department of King's College, New York city, was organized with a complete faculty, in 1767, and the first regular degree of M. D. in the colonies was conferred upon Samuel Kissam, in March, 1770, by that school, the degree of M. B. having been conferred upon him the preceding year. King's College has become the famous College of Physicians and Surgeons of New York. Toner says: "The honorary degree of M. D. was conferred upon Daniel Turner by Yale College in 1720 As Doctor Turner had been a liberal benefactor of the college, the M. D. was facetiously said to signify *multum donavit.*"

The medical department is a most important component of an army, and until very recent years it had received scant consideration. Of course at the time of the Revolution there was no organization whatever, and commissary and equipment materials were almost impossible to obtain, but the medical department was even worse off, for no medical supplies could be had. The few instruments and drugs that were obtainable came mainly from the surgeons' very limited private store. Many of the surgeons were appointed without reference to skill or ability, so that altogether the condition of the medical department was most lamentable. As an evidence of the little material to be had, the "razor" letter from Surgeon General John Morgan, just befor the battle of Long Island, in August, 1776, will illustrate:

Sir:—I have sent to the surgeons, desiring the youngest off duty to go to your assistance, and take four mates with him: to carry over five hundred additional bandages, and twelve fracture boxes. I fear they have no scalpels, as whatever I have committed to the hospitals has always been lost. I send you two, in which case, if you want more, use a razor for an incision knife. Let me know, from time to time, at Long Island. J. Morgan.

To Dr. Warren, Surgeon of the General Hospital at Long Island.

The following extract from *Thacher's Military Journal* for October 24, 1777, will give an idea of the acuteness of intelligent observation on the part of the American surgeon. Referring to the hospital at Albany, he says:

This hospital is now crowded with officers and men from the field of battle. Those belonging to the British and Hessian troops, are accommodated in the same hospital with our own men and receive equal care and attention. The foreigners are under the care and management of their own surgeons. I have been present at some of the capital operations and remarked that the English perform with skill and dexerity, but the Germans, with a few exceptions, do no credit to their profession; some of them are the most uncouth and clumsy operators I ever witnessed and appear to be destitute of all sympathy and tenderness toward the suffering patient. Not less than one thousand wounded and sick are now in this city; the Dutch Church and several private houses are occupied as hospitals. We have about thirty surgeons and mates, and all are constantly employed. I am obliged to devote the whole of my time, from eight o'clock in the morning to a late hour in the evening, to the care of our patients. Here is a fine field for professional improvement. Amputating limbs, trepaning fractured skulls, and dressing the most formidable wounds, has familiarized my mind to scenes of woe. A military hospital is peculiarly calculated to afford example for profitable contemplation and to interest our sympathy and commiseration.

Dr. James Tilton, who was left in charge of the American sick and wounded at Williamsburg, Virginia, after the surrender of Cornwallis at Yorktown, the French troops being encamped at the same place, in his Observations on Military Hospitals, says:

Being thus in a French garrison I had some opportunity of observing the French practice and management of their sick. In passing the wards of their hospital, their patients appear very neat and clean, above all examples I had ever seen. Each patient was accommodated with everything necessary, even to a night cap. Nevertheless, they were not more successful than we were. Even their wounded, with all the boasted dexterity of the French to aid them, were no more fortunate than ours. I was led to attribute their

failure principally to two causes. For ease and convenience, they had contrived a common necessary for their whole hospital, the college, a large building three stories high, by erecting a half hexagon, of common boards, reaching from the roof down to a pit in the earth. From this perpendicular conduit doors opened each floor of the hospital; and all manner of filth and excrementitious matters were dropped and thrown down this common sewer into the pit below. This sink of nastiness perfumed the whole house very sensibly and, without doubt, vitiated all the air within the wards. In the next place their practice appeared to me to be very inert. When passing their wards with the prescribing physicians, I observed a great number of their patients in a languid and putrid condition and asked occasionally if the bark would not be proper in such cases. The uniform answer was no, too much inflammation. And when they attended my round of prescription and saw me frequently prescribing the bark, in febrile cases, and even for the wounded, they lifted up their hands in astonishment. Few or no chemical remedies were employed by them. One of their regimental surgeons declared that he never used opium. Their hospital pharmacopœia consisted chiefly of ptisans, decoctions, and watery drinks, fitted only for inflammatory disorders. All these circumstances considered, satisfied my mind why their ample accommodations gave them no advantage of us in the result of practice. I was the more surprised as Doctors Cost and Borgelli appeared to be men of science, well qualified to make research.

During the Revolution the practice of medicine was at a low ebb, both because of the incompetence and dishonesty of most of the surgeons, and the lack of necessary drugs and essential supplies. The following extract from a letter of Washington to Congress in the autumn of 1776 gives his estimate of the surgeons of the army:

No less attention should be paid to the choice of surgeons than other officers of the army. They should undergo a regular examination, and if not appointed by the Director-General and surgeons of the hospital, they ought to be subordinate to and governed by his direction.

The regimental surgeons I am speaking of, many of whom are very great rascals, countenancing the men in sham complaints to exempt them from duty, and often receiving bribes to certify indispositions with a view to procure discharges or furloughs.

But independent of these practices, while they are considered as unconnected with the general hospital, there will be nothing but continual complaints of each other—the director of the hospital charging them with enormity in their drafts for the sick, and they him for denying such things as are necessary. In short, there is a constant bickering among them, which tends greatly to the injury of the sick, and will always subsist till the regimental surgeons are made to look up to the Director-General of the hospital as a superior. Whether this is the case in regular armies or not, I cannot undertake to say; but certain I am, there is necessity for it in this, or the sick will suffer. The regimental surgeons are aiming, I am persuaded, to break up the General Hospital, and have in numberless instances drawn for medicines, stores, etc., in the most profuse and extravagant manner for private purposes.

To illustrate the scarcity of food and hospital supplies in 1778 the letter of Dr. John Warren is quoted:

To His Excellency the Governor and the Honorable the Council of The Commonwealth of Massachusetts:

Gentlemen—Though I have frequently represented the distressed condition of the sick in the Continental Hospital, yet I have never had so ample occasion to deplore their miseries as at present.

For some days they have not had an ounce of meat; not a stick of wood but what they have taken from the neighboring fences; for near a week not a vegetable; and scarcely any medicine for above a year. In fine, to sum up the whole in a few words, the sick and wounded, many of which are exceedingly dangerous, and some of them in a state which requires immediate amputation, are not furnished by the public with a single article of sustenance except bread alone, and must have perished ere this had not the charitable donations of a few individuals in some measure contributed to their relief. I have been incessantly making application for these last twelve months to all the departments for supplies, but cannot procure any. During which time the groans of the sick and wounded, suffering and perhaps dying, for want of necessities, have been perpetually saluting my ears. I must, therefore, beg your Excellency and Honor's action in this matter, and am with the greatest respect, gentlemen,

Your most obedient servant,

J. Warren.

With the close of the Revolutionary War there was a quickening of enterprise and medicine received its degree of stimulation too. The College of Philadelphia was merged with the University of Pennsylvania and the medical department went forward with renewed energy and success. In 1783, Harvard Medical School began its honored career. Medical societies were formed and every energy that tended to forward medicine in this new era was active. There were no startling events in medicine in this country in the eighteenth century. Not many papers and few books were written. But the medical men were keen observers and alert to avail of all progressive means. Considering the period—the remoteness of the new country and its difficulties, not much could be expected.

3 Thomas Circle.

RADIOTHERAPY IN CHRONIC ARTHRITIS.

By Ernest Zueblin, M. D.,

Baltimore,

Professor of Experimental and Clinical Medicine, University of Maryland.

(A Report from the Medical Clinic of the University of Maryland Hospital.)

In the treatment of such a chronic disease as arthritis, medication with salicylic acid and its derivatives would seem the most rational. If for the same disease, instead of one specific remedy, so many others are recommended, the multiplicity of therapeutic means would suggest that the practical therapeutic results thus far obtained make it desirable to improve the methods of treatment. In accordance with the progress of science today, we are surprised by the various nocent influences, bacterial (1), toxic (2), nutritional and metabolic (3), which are supposed to constitute the basis of such a disease.

Admitted that all these factors are etiological, the treatment necessarily cannot be uniform in all instances. If in former years a few writers did not approve the general opinion of the specific action of the salicylic compounds in chronic arthritis (4), a perusal of the literature suggests that lately the discussion has again been opened, when and how the salicylates fail to fulfil our therapeutic expectations (5).

A detailed discussion of such an interesting problem cannot be given at this time without increasing unduly the length of the present communication. Only a few facts may be recalled which are liable to change our opinion as to the specific action alleged for the salicylic compounds. Experimental study of the prophylactic and curative effect of sodium salicylate in animals infected with virulent strepto-

cocci has failed so far in the proof of the specific and superior therapeutic action of the sodium salt (6). Expecting that other investigators will add more facts, it would be interesting to learn of the individual experiences of the general practitioner.

More than ever are we impressed by the necessity for careful examination and supervision of the cases (7), since the prescription of antirrheumatics alone, even if the patient can be trusted with the careful fulfillment of the medical instruction, is not sufficient to obtain cure or relief.

Whether such a failure is due to the dose of salicylates given is not settled as yet: different suggestions have been made (8), new methods of administration, rectal, intramuscular, intravenous, cathaphoretic, have been advocated (9). Even without the use of the salicylates favorable results were obtained by phenol injections (10), formaldehyde (11), intravenous administration of mercuric chloride (12), different extracts from endocrinous glands (13), dietetic measures (14), beside the various applications of physical means, including radiotherapy (15).

The list of therapeutic methods has been further increased by the use of different vaccines (16), and with such a variety of recommendations, including surgical help, it would seem difficult to select just the proper method of treatment. Medical progress is not reached all at once: little by little we learn to treat cases properly, so that the following clinical data may be of interest to the general practitioner:

Case I. I. B., aged thirty years, laborer in a tin factory, married, had several attacks of gonorrheal urethritis, a sore on his penis, multiple articular rheumatism since 1903. Patient came to the University of Maryland Hospital, on September 10, 1913, with the complaint of severe pains in his knees, ankles, wrists, fingers, backache, inability to walk, headaches, dizziness, anorexia, occasional nausea, yellow discharge from the urethra. The articular manifestations were particularly aggravated since August 17, 1913.

The physical findings of interest were the involvement of the following joints with redness, swelling, impaired motion, local rise of temperature: Sternoclavicular, right and left shoulder, right and left knee, left elbow, wrist, and the second, third, fourth and fifth metacarpophalangeal joints of the left hand, both ankles, tenderness of the right cervical muscles (sternocleidomastoid, etc.) and of the entire spine, hypertrophy of prostate, active urethritis, with many intracellular gonococci. The urine had a trace of albumin. Blood: Hemoglobin eighty-three per cent., 16,866 white blood cells, polynuclears fifty-nine per cent., small lymphocytes twenty-nine per cent., large lymphocytes eleven per cent., eosinophiles one per cent. Blood culture negative, complement fixation for gonococci negative, on September 28th, at a later date (February 21, 1914) positive; Wassermann reaction and Nogucki test negative.

This patient, from September, 1913, to January 24, 1914, received the following treatment: Hexamethylenamine grains five, three times a day, sodium salicylate grains fifteen every six hours, aspirin grains five every two hours, two injections of antigonococcic serum of one c. c. each; local applications to the joints involved, with chloroform liniment, Stokes's liniment, oil of gaultheria, sodium cacodylate, local irrigations of permanganate of potassium one in 6,000.

This treatment had not the slightest effect, so the first attempt was made to treat the patient by local applications of radiothorium contained in a sealed glass tube. This tube examined under the fontactoscope emanated through the glass container 90,000 maché units an hour. Previous to that application physical examination of the left knee showed considerable swelling; infiltration, tenderness on touch, remarkably reduced motility, thickened capsule. The patient was hardly able to bend his knee on account of the pain and the inflamed condition of the joint.

The radiothorium tube was applied to the upper cul-de-sac of his left knee, fastened by adhesive plaster, and remained there for two hours. The patient noticed an immediate improvement of his pains; he was able to move his joint. This treatment, excluding internal medication, was continued on the following days. Examination, two days later, showed less swelling, the outlines of the joint were better defined, the infiltration of the upper cul-de-sac was less pronounced, and slight spontaneous pain upon pressure could be observed. The lateral parts of the joint, which had not yet been exposed to the treatment, showed no improvement whatever. The radiation tube was therefore applied for the same length of time. The result was, that the patient had no more pain in his knee, the swelling and periarticular infiltration had considerably diminished; the patient, who before maintained his knee in a forced extension, could bend it and walk without much difficulty.

After these favorable results with radiothorium a similar attempt was made with the application of radiating energy to the wrist and metacarpophalangeal joints of the upper extremities. The average duration of this treatment was from two to three hours a day, 180,000 to 270,000 maché units. A similar improvement was observed as regards spontaneous and provoked pain during motion, swelling, infiltration, local tenderness, and gain in motility of the affected joints.

It would lead too far to give all the details of the clinical improvement of the patient's condition during radioactive treatment, which was continued for a various length of hours, according to the condition of the joints involved. As a summary, the knee was exposed to radiothorium for ten hours—900,000 maché units; the right and left wrist and fingers seventy-two hours—64,800,000 maché units; the elbow forty-seven hours—42,300,000 maché units.

It seems that, according to the extent of the morbid process, the joints differ in their reaction after being exposed to radiotherapy. In some instances, as for the wrists, the elbow in this particular case required several treatments before subjectively or objectively any change could be noticed.

The improvement in the patient's condition was striking, if we consider that during the first period of treatment at the hospital, from September, 1913, to January 24, 1914, the patient was greatly troubled by the pains in his joints, the swelling, thickening, and tenderness of the capsule, which made the movement of these joints hardly possible, and if we follow the improvement which succeeded the radiotherapy after January 24 up to March 6, 1914, we must attribute a therapeutic action to the radiothorium application. The patient left the hospital

considerably improved locally, subjectively, and objectively; having lost his pains, he was able to use his limbs, and he could walk.

Case II. C. G. (Ward D, No. 18), colored, sixty years old, fireman on a steamboat; widower; complained of a deformity in his hands and fingers, which had been gradually getting worse for the past few years. From his past history we learned of his previous acute infections by the following diseases: Measles, whooping cough, mumps, smallpox, malaria, and acute articular rheumatism every winter for the past ten years. Joints were painful, swollen, with reduced motility. At first the attacks were situated in the larger joints and only later were the small joints involved. Patient was alcoholic, used all kinds of stimulants without moderation. Considerable constipation; no digestive disturbances; easily inclined to colds, pretended to have spit up blood occasionally. Slight dyspnea upon exertion, palpitation of the heart, but no edema of ankles. No urinary disturbances; frequently subject to headache.

Among the physical findings the following were of interest: Sluggish reaction of pupils, moderate paresis of the left lower facial nerve, very bad condition of the teeth, marked pyorrhea, tremor of tongue, congestion of posterior pharyngeal wall and fauces. Enlarged cervical glands, chronic endocarditis with zone of hypertrophy and dilatation.

As to the extremities, both shoulders presented tenderness on pressure and pain on slight movements, with thickened capsule, moderate tenderness on pressure over both elbows, thickened capsule, impaired flexion and extension, limited supination and pronation. Lateral deviation of the fingers of the left hand, involving the second, third and little fingers, partial ankylosis of the middle and end phalanx, skin glossy, ankylosis of the interphalangeal joint of the middle finger, lateral deviation of the phalanges, thickened capsule and enlarged head of the first interphalangeal joint of the index, marked tenderness with moderate crepitation.

The right hand showed glossy appearance of the skin, lateral deviation of the fourth finger, enlarged metacarpophalangeal joint, thickened capsule of both interphalangeal joints. Tenderness, middle finger thickened, heads enlarged, no rise of local temperature, swelling, tenderness of the joints of the index. Wrists of both sides enlarged in the lateral direction, swelling, tenderness, thickening of the capsule with pain on motion, moderate flexion and extension, with crepitation. Hip joints of both sides are found in good condition, absence of pain, tenderness, swelling and diminished motility. Knee joints very painful to touch, with impaired flexion and extension, ligaments and perarticular structures thickened but no swelling noticed. Ankles stiffened, painful on flexion and extension, movements limited, slight thickening of the capsule and of the ligaments; crepitation present. Metatarsophalangeal joints of both feet enlarged in all diameters; limited flexion and extension with crepitation, which existed also in the metatarsal and phalangeal joints.

Vertebral column: Extension and flexion in dorsal lumbar region limited but not painful. Cervical region normal.

The rheumatic pains being particularly pronounced in the right wrist and in the second to the fifth metacarpal phalangeal joints, mesothorium was applied for two hours each day (180,000 maché units). The immediate result was satisfactory, followed by quick disappearance of the inflammatory swelling, of the tenderness, and by return to almost normal motility, without causing pain.

The knees were also treated similarly; before treatment they presented considerable pain, tenderness, swelling, and lack of motility. On the one knee mesothorium radiation (180,000 maché units) was applied for two hours each day; to the other knee a compress of radioactive magnesium sulphate solution was applied for several hours. Following the medication on either side, the patient soon experiences distinct relief, which was evidenced objectively by considerable reduction in the swelling and tenderness and gain in motility, without distress or pain.

This radiotherapy was repeated daily for four hours (360,000 maché units a day) for about three weeks without internal medication of salicylates or other drugs. Subjectively the patient felt very well satisfied; objectively, the fluid in the knees had disappeared, the articular capsule presented less infiltration, and on pressure no pain nor discomfort could be noticed.

Case III. P. M. (Ward G, No. 9), aged forty-two years, marine fireman, single, white. Complaint, "rheumatism" of right elbow, left knee, and left foot, due to exposure, to sudden changes of temperature from the heat of the engine room to the changeable weather conditions on deck, enhanced by perspiration and insufficient clothing. Moderately alcoholic and a smoker. Family history: Father living and well; mother dead, aged forty-eight years, of heart disease; one brother and one sister living and well. One sister died of tuberculosis when nineteen years old; patient during two years lived with his sick sister. No history of malignant disease in family. Past history: Children's diseases as follows: Measles, mumps, whooping cough. Other infectious diseases negative. About twenty years ago patient had inflammation of the right lung, kidney, gastrointestinal disturbances, sciatica. Three months ago, suffered from dysentery for two weeks. Luetic or gonococcic infections denied.

Present illness began about September 17th. While at work, noticed sharp localized pain in right elbow, which persisted with the same character and intensity until now. For two weeks patient complained of similar pains at the lower part of his spine, left knee, and lately in the left foot. Four days ago, like complaints in the right ankle, with swelling. No history of injury to the joints. Absence of chills or sweats, except when in the engine room. The sleeping quarters in the forecastle were very cold; worked in shifts of four hours and usually felt cold. Negative history as to the circulatory, respiratory, gastrointestinal tract, genitourinary, and nervous systems.

Physical findings: Atrophy of muscles of the left thigh and leg. Brown discoloration of skin of upper third of leg, and scar on the anterior surface of tibia. Skin not adherent to subcutaneous tissue. Roughened tibia at that level, contrasting with right leg, which was normal. Upper and lateral culs-de-sac of left knee prominent, distended by fluid. White scar below the inner condyle. Fair amount of fluctuation, capsule distended and thickened, particularly in upper sections of joint. Both menisci normal, not tender nor swollen. Flexion of the knee reduced to an angle of 125°. Active extension of the knee performed very slowly, accompanied by a dull aching pain in the knee. Passive flexion impaired to about the same extent. Left hip joint normal. First metatarsal phalangeal joint swollen and thickened, with cracking sounds during motion. Right knee normal in every respect. Muscle contraction of the left thigh considerably weaker compared with right side. Left inguinal glands considerably swollen and tender, normal on the opposite side, except slight swelling.

Right elbow in, flexion and inward rotation, total extension impossible, leaving still an angle of about 150°. Marked wasting of muscles of upper arm. Diffuse swelling of elbow, especially at level of epicondyle and capitulum radii, considerable tenderness of the capsule and ligaments, particularly of external condyle. Enlarged epitrochlear gland. Considerable thickening of capsule, more on external condyle than on inner side; periarticular infiltration with tenderness. Passive flexion possible as far as an angle of 100° with considerable resistance. Reduced pronation and supination, particularly during outward rotation. Shoulder joint normal. Axillary glands on right side enlarged. Normal condition for left elbow, wrists, and remaining joints. Cervical glands on both sides enlarged. Moderate tremor of fingers. Teeth in very bad state of preservation, with worn-out surface of mastication (pipe).

Laboratory findings: Urine, amber color, acid reaction,

specific gravity 1020. Albumin and sugar negative. Few pus cells, no casts. Urea 3,0 grams. Blood, hemoglobin eighty-five per cent., leucocytes 8,400, Wassermann test negative.

Medication: On admittance sodium salicylates fifteen grams every four hours. No relief being obtained after two days, the internal medication was stopped entirely and replaced by compresses of saturated magnesium sulphate solution to elbow, and mesothorium treatment to knee.

Bedside notes next day (October 10th): Pains in right elbow considerably relieved, swelling and tenderness reduced. Left knee treated for two hours each day with mesothorium tube (180,000 m. u.) to upper and lateral cul-de-sac. Slight erythema of the skin, motility of the joint seemed increased and less painful; local tenderness less marked.

October 12th, left knee swelling less noticeable, hardly any tenderness produced by touch, pressure, and motion. Motility more extensive. Slight tenderness on deep pressure upon inner lateral ligament. Right elbow swelling had disappeared, extension and flexion increased and less painful. October 17th, left knee infiltration much less noticeable, hardly any pain, spontaneous or on motion; circumference of left knee cap 14¼ inches, upper cul-de-sac 14⅛ inches. Right elbow swelling no longer present, pain greatly diminished, improvement noticed in every way. October 18th, mesothorium application extended to three hours on each side of knee. October 24th, mesothorium applied also over patella. Patient advised to make passive and active exercises for his elbow in raising a slight weight attached to foot of bed. October 27th, left knee, less infiltration and swelling, outlines of the patella very noticeable. Slight degree of fluctuation. Infiltration of the articular capsule markedly less. No pains spontaneous nor on deep pressure and forced motion. Flexion and extension of knee had decidedly gained, extension of knee as far as possible to 100°. Menisci not enlarged and not more tender. Inguinal glands diminished in size and not more tender.

Right elbow swelling considerably lessened, capsule had become normal, no pains spontaneously nor provoked by pressure and palpation. Increase of extension about 15°, compared with initial statement. Flexion hardly surpassed right angle. Bones no longer tender. Condition of teeth still poor; pyorrhea, however, less marked.

During the first eleven days of the patient's sojourn at the hospital he had a moderate subfebrile temperature, varying from 100.40 to 98.40 F.; pulse was from seventy to ninety-eight on the average; after that temperature and pulse remained normal. Only the articular manifestations could explain these facts, since physical examination of the rest of the body revealed nothing abnormal.

Epicrisis. In this patient, affected with subchronic arthritis of the right elbow and left knee, considerable improvement was obtained by external applications of concentrated magnesium sulphate solutions and radiotherapy. Subjectively and objectively the inflammatory symptoms subsided and motility was improved. The radiotherapy to the left knee was applied for ninety-six hours, giving an energy of 8,640,000 maché units for twenty days. The magnesium sulphate therapeutics was equally satisfactory; the results perhaps were not as rapid as with the mesothorium applications, while the salicylates did not cause any appreciable improvement.

Among my observations I will briefly mention Case IV.

Case IV. J. O. C., twenty years old, cartoonist, in August, 1914, acquired a Neisser infection. Vaccine and local treatment gave partial relief, to which manifestation arthritis of the elbow and the phalangeal joints was added. The ordinary methods of treatment remained without success, so the patient entered the hospital. The elbows and small phalangeal joints presented considerable infiltration, swelling, tenderness, impaired active and passive motion, and considerable pain.

Salicylates in high doses did not afford the slightest improvement, so a trial was made with mesothorium applications over some of the affected joints; the other joints, receiving no treatment, served as control. Immediate and lasting relief of the local objective and subjective symptoms resulted, while the control joints did not show the slightest improvement. Once this result was obtained, the mesothorium tube was omitted entirely, and a trial was made with the application of compresses of radioactive magnesium sulphate solution to the joints as yet untreated and still involved. Within twenty-four hours considerable improvement could be noticed, as the swelling, tenderness on pressure and impaired motility had been reduced, and spontaneous pain was no longer present.

This favorable change persisted and maintained itself during the successive days, and as a general result the patient, who before the radioactive treatment had remained stationary for at least three weeks, was discharged, markedly improved. Although slight tenderness of both heels was noticed, no special application was made to these latter parts, as the complaints were not such to justify a local treatment. The patient was seen four months later; the treated joints remained well, while for the yet untreated heels local corpuscular radiotherapy was successfully applied; a report will be presented later.

Case V. J. B., Owings Mills, fifty-eight years old, married, night guard at Home for Feebleminded. Admitted November 14, 1914, discharged December 23, 1914. Complaint, inflammatory rheumatism.

Family history: Father died at age of twenty-seven years of cholera morbus; mother twenty-three years of pneumonia; one brother in infancy; one half-sister at age of fifty-one years from gallstones operation. Wife died at age of fifty-seven years, insane; four children living and well, one died in infancy of intestinal disorders. Wife had no miscarriages. Past history: Had scarlet fever in 1856, complicated by cellulitis of neck and cervical adenitis; glands breaking down, abscess formation, and rupture. Measles, chickenpox, whooping cough, uncomplicated, during childhood. In 1883 tonsillitis; in 1891, influenza, uncomplicated; in 1892, typhoid with myalgia. Patient said he had had four attacks of pneumonia, each of one week's duration. Had had countless attacks of malarial fever while living on the eastern shore of Maryland, not attended by complications or sequelæ. Venereal history negative.

Present illness dated from end of September, initiated by tiring of his legs and soreness of his feet. Work was continued until acute symptoms in the right knee appeared as follows: Rise of local temperature, swelling, redness, pain on touch and on motion. Several days later, left knee became involved, then left ankle and both shoulders; elbows and wrists becoming involved alternately and showing the same symptoms as noted above; the intermaxillary and the small and clavicular joints were never involved. Fever and sweats observed during the first days of his disease; absence of herpes. Patient admitted a similar attack of "rheumatism" twelve years ago (1902) of mild character, so that he was not obliged to discontinue his work. Alimentary tract: Digestion impaired for about twenty-six years, often associated with pains along the costal margin, increased by intake of food.

Pulmonary findings negative Heart, except palpitation, nothing in particular noted. Urinary symptoms: At present time some trouble at micturition, ardor urinæ, no undue frequency. Nervous manifestations negative.

Physical examination: Teeth in extremely poor condition, numerous cavities, extensive pyorrhea, slight tremor of tongue, moderate anemia of lips and the mucous membranes, thorax emphysematous. Respiratory movements

fair, hyperresonance on percussion, harsh breathing over both apices, more pronounced over the right side.

Heart, apex beat not visible nor palpable. Sounds very distant, faint, hardly audible, regular, maximum tension; fifth intercostal space, 3½ inches from the midsternal line, distinct accentuation of second pulmonic. Absence of murmurs and shocks.

Examination of joints on date of entrance to the institution; showed, over the buttock below the tuberosities of the iliac bones on right side, a tumor about the size of a hen's egg, freely movable with the tissues, slightly reddened, painful, and tender. Symmetrically, on the left side, a larger mass (size of an orange), fixed, hard, painful, tender, with induration of the surrounding tissues. Rectal examination negative except enlargement and thickening of the prostate (perirectal or gluteal abscess?).

On entrance, both shoulders, both knees and ankles were very tender on pressure; no particular swelling, the previous redness, according to patient's statement, having disappeared. Right knee normal, left knee painful on forced movements, enlargement of the bones, thickened capsule, patella mobile, crepitus, but no fluid. Ankles seemed normal. Joints of the hands: Fingers enlarged, thickened, with lateral outside deviation. Transverse diameter of both wrists seemed enlarged by diffuse swelling which extended to the lower third of both ulnas, markedly painful on the slightest touch and on motion. Both shoulders painful on deep pressure and upon hyperabduction. Reflexes could not be tested on account of great tenderness.

Laboratory findings November 15th. Urine, specific gravity 1.013, albumin negative; acid reaction; except a few epithelial cells and calcium oxalate crystals, nothing particular found in sediment. November 20th, total amount 1,000 c. c., specific gravity 1.012, trace of albumin, no casts, sugar, urea 11.52 grams. December 18th, specific gravity 1010. albumin and sugar negative.

Blood examination on November 16th: Hemoglobin, 90 per cent.; leucocytes, 12,800; polymorphonuclears, 68; small mononuclears, 21; large mononuclears, 2; transitionals, 7; eosinophiles, 2; basophiles, 0.

At entrance of patient to the hospital, sodium salicylate grains ten three times a day, were given for two days, but as no evident improvement was noticeable, radioactive magnesium sulphate solution was applied to both wrists and ankles and repeated every four hours. Already, on the following day, the application of compresses of magnesium sulphate solution yielded considerable relief. On November 23rd, the left knee and ankles are also improved locally, there being no swelling nor fluid; the capsule was slightly thickened and cracking sounds were still noticeable in the left knee. On November 25th, patient is out of bed and walks for a short time.

On December 2nd, the magnesium sulphate medication is discontinued entirely; patient feels very comfortable. On December 12th, the deep seated abscesses in both gluteal regions are opened and drained.

On account of his heart, which is found enlarged, the additional prescription of infusion of folia digitalis two drams, thrice daily, is given, which medication, two days later, did not seem to benefit the patient materially, wherefore pituitrin, as recorded on December 22nd, was given. Patient left the hospital decidedly improved with regard to his articular and cardiac manifestations.

From the preceding reports of cases, where the ordinary antirheumatic remedies did not produce the desired therapeutic effects, we learn that radioactive substances, such as mesothorium locally applied to diseased joints, is apt to produce a remarkable change in the subjective and objective symptoms of acute chronic and deforming arthritis. Not only is pain relieved by the local application of radiating energy, but also the infiltration of the articular and periarticular structures becomes less noticeable, and a reduction of the synovial fluid, and a gain in the active and passive motility are noticed. The danger of ankylosis, so frequent a consequence of the acute and chronic forms of rheumatism, resulting from the immobility of the joints engendered by the pain, can and should be overcome by radioactive treatment whenever the ordinary internal medication proves unsatisfactory.

In the course of the past few years our knowledge of the curative effect of highly radioactive substances in acute and chronic joint affections has been increased by various contributions. Although the number of domestic authors is small (see literature in my previous papers, 15) compared with those found in foreign literature, the therapeutic utility of radium and thorium in these instances can no longer be ignored by the profession. In dealing with a most frequently chronic course of the disease, sequelæ of which remaining unchecked do not add to the fame of our therapeutic achievements, it must be the aim to find and adopt new means of reducing these inconveniences.

Admitting that the highly radioactive substances, radium and mesothorium, merit application in rheumatism, it may seem strange that magnesium sulphate solutions, which can be rendered radioactive, should produce similar therapeutic results. Although the proof of such a statement will be given in a later article, even now I wish to say that between radium, mesothorium, and magnesium sulphate there seems to exist a physical similarity, which difference appears to be one of quantity, rather than of quality.

So far as my studies along that line have advanced, I am inclined to say that this difference is also expressed in the biological effect, where the rapid and longer lasting effect must be expected from the more radioactive and fresh preparations.

TOLUOL.

Its Value in the Sterilization of Vaccines Made from Nonsporogenous Gram Negative Bacteria.

By Leverett Dale Bristol, B. S., M. D.,
University, N. Dak.,
Professor of Bacteriology and Hygiene, University of North Dakota; Director, State Public Health Laboratories.

INTRODUCTION.

The value of well prepared vaccines in the prevention and cure of certain bacterial infections has been quite universally demonstrated. Such vaccines consist of measured quantities of dead bacteria suspended in salt solution. Most authorities agree that the highest grade of immunization follows the use of living or "attenuated" bacteria, but the danger of spreading or increasing infection thereby has prevented the use of this method on a large scale.

Undoubtedly the most important step in the preparation of a vaccine is the killing of the bacteria, for the immunizing power of the vaccine may be greatly impaired by careless or improper methods. As a rule, bacteriologists and immunologists have followed the example of Wright (1) in subjecting the salt solution suspension of bacteria, in a water bath, to a temperature of 60° C., for an hour on one or more days. Some workers prefer a lower temperature, such as 55° to 56° C., recommended by Russell (2) in the preparation of antityphoid vaccine, or 53° C., as recommended by others. Instead of killing bacteria by heat, a few have preferred to depend on the germicidal effect of such chemicals as phenol or tricresol, highly diluted, both to sterilize and to preserve vaccines. With the heat method of sterilization, one of the latter chemicals has generally been added as a preservative.

It has been fairly well established that overheating reduces or destroys the power of vaccines to stimulate antibody formation. Also, it has been demonstrated that bacteria, or even strains of the same organism, may differ in their thermal death points. It is quite certain that as a rule typhoid bacilli are killed at a temperature below 60° C. Metchnikoff never believed that heat-killed vaccines are the most efficient.

The purpose of this study has been to find a method of sterilizing vaccines satisfactorily without heat. It has been noticed by the writer that such chemicals as phenol and tricresol, unless used in considerable strength, vary considerably in their germicidal effect on vaccines, and that in addition to the use of high dilutions of these agents, a final heating of a vaccine is often necessary to bring about sterility. It is true that a strong solution of these chemical agents is effective in killing bacteria, but it has been noticed that vaccines thus prepared are not so effective in the process of immunization. Furthermore, several instances of marked tissue injury have been noted at the sites of inoculation following the use of vaccines to which such irritating chemicals have been added.

Our object, then, has been to find a chemical agent, bland in character, which has the power of killing bacteria, but which does not materially affect their antigenic properties; that is, to get as "live" a vaccine as dead organisms can provide. Such an agent, at least for the killing of nonsporogenous Gram negative bacteria, is toluol, which the writer (3) has been using for some time in keeping cell enzymes free from bacterial growth in connection with his study of experimental cancer.

DEFINITION AND HISTORY OF TOLUOL.

Toluol is a hydrocarbon of the benzene series, having the chemical formula $C_6H_5CH_3$. This hydrocarbon (also known as toluene, methylbenzene, or phenylmethane), was discovered many years ago by Pelletier and Walker (4) as a byproduct of illuminating gas made from the resin of pinus maritima, and first named by them retinaphtha. The same hydrocarbon was later obtained by Deville (5) in the distillation of resin of tolu balsam, and was named by him benzoene. Later, Berzelius (6) gave this hydrocarbon the name toluol. It may now be obtained on a large scale from the distillation of light coal tar oil.

Toluol is a very light, volatile, refractive, colorless liquid, having an aromatic odor like that of benzene; it boils at 110.3° C., and freezes at —93° C.; the specific gravity at 0° is 0.882. On oxidation it is converted into benzoic acid. In full strength toluol is quite bland, causing no irritation of tissue. It does not hold or mix with water in solution and always rises to the top when the two are combined. Benians (7) has observed that toluol has a germicidal action on many bacteria, especially those of the Gram negative nonsporogenous organisms, and also to a considerable degree on tubercle and diphtheria bacilli, and streptococci.

ACTIONS OF CHEMICAL ANTISPETICS AND HEAT ON LIVING CELLS.

Chemical antiseptics may be divided, according to Buchner and Rapp (8), into two classes, depending on their action on living protoplasm. In the first class they place those which combine chemically with the protein constituents of the cell, such as salts of copper, silver, mercury, cyanides, fluorides, etc. The second class consists of antiseptics which do not combine with the protein constituents, such as chloroform, ether, phenol, thymol, and toluol. Their action probably is due to their solubility in the fat of the cell, and the alterations set up in the lipoidal plasma skin. It is supposed that the plasma itself undergoes change subsequent to the penetration of the plasma skin by the antiseptic, and that the dissolving of cell lipoids destroys cell substances necessary to life and growth.

It was early demonstrated that these antiseptics

of the second class killed practically all nonsporogenous organisms, so far as growth and reproduction are concerned, without apparently injuring the active cell contents, such as enzymes and toxins. Because toluol apparently has the weakest effect on enzymes of all the above named antiseptics, E. Fischer introduced it to keep enzyme solutions free from bacterial growth. In contrast to the harmless action of toluol on cell enzymes and toxins, most of these important bodies (which have so much to do with cell metabolism, growth, reproduction, and poisonous effects) are destroyed by temperatures ranging from 55° to 75° C. The longer the time in which they are subjected to such heat, the more certain is their destruction. Are not these facts of considerable importance in connection with the problem of vaccine sterilization? If we desire the enzymes and toxins in full strength to stimulate the formation of antienzymes and antitoxins, we must use heat very carefully or not at all in killing bacteria for vaccines.

METHOD OF STERILIZING VACCINES BY TOLUOL.

A pure culture of the bacteria from which the vaccine is to be made is inoculated upon the slant surface of plain agar medium and incubated at 37° C. for eighteen to twenty-four hours. When sufficient growth has taken place, enough toluol is run into the tube so that the entire surface of the medium containing the bacteria is covered. The toluol is allowed to remain in contact with the bacterial growth for variable periods of time, according to the nature of the organisms to be killed. As a rule most of the Gram negative, nonsporogenous bacteria will be killed in twenty-four hours. After the toluol has been allowed to act for the necessary time it is poured off into a container for "waste" toluol (for the sake of economy), which may be subsequently filtered and used on other cultures. The agar slants containing the killed cultures are then replaced in the incubator for a short time to hasten the complete evaporation of the few remaining drops of toluol. Because of the extremely volatile character of this hydrocarbon the dead culture will be completely and quickly dried without the formation of a residue. Subcultures are then made to control the sterility of the vaccines, after which sterile salt solution is added and the dead culture carefully scraped off the medium into suspension in the salt solution. At this point a sufficient amount of the suspension is withdrawn for the counting of bacteria, which may be done according to the method of choice. If the toluol has not had too long an influence on the bacteria, the latter retain their size, shape, and staining qualities so that they may be satisfactorily seen and counted by the usual methods.

ABNORMAL LABOR.*

Some Essentials in Its Management.

By Solomon Wiener, M. D.,
New York,
Associate Gynecologist, Mount Sinai Hospital.

This subject is so large and so complex that it seems almost impossible to do it any sort of justice in a brief space. The sins both of omission and of commission which are perpetrated in the management of abnormal labor are so many, and their consequences are so readily fraught with disaster, that the cardinal principles which should govern our practice in this most important field cannot be reiterated too often, be it ever so briefly. I shall limit my remarks to those cases of abnormal labor in which there is no distinct abnormality of the pelvis or of the shape of the fetus—no fetal monstrosity—and the pelvis is of normal, or approximately normal, size, and configuration. It would be impossible to include the subject of pelvic deformities in this brief discussion.

EXCESSIVE UTERINE CONTRACTIONS.

With a normal baby and pelvis excessive contractions usually spell precipitate labor. The treatment as a rule consists in—repairing the damage! If the doctor is so fortunate as to arrive on the scene before the baby does, he can diminish the force of the contractions by the administration of small quantities of ether or chloroform with each pain. Keeping the patient on her back, or even in a slight Trendelenburg posture, will aid in the protection of the perineum from serious injury. It is unwise to give a sufficiently large dose of morphine to diminish the strength of the contractions in these cases. Morphine given shortly before the birth of the child is not eliminated with sufficient rapidity by the mother's excretory organs; the child's respiratory centre will be markedly depressed, and it may be born in a state of deep asphyxia.

UTERINE INERTIA.

This subject has acquired renewed interest in recent years because of the widespread abuse of pituitary extract. The discovery of its remarkable action upon the parturient uterus has been perhaps the greatest single addition to the obstetrician's armamentarium in recent decades; but like every other good thing it is vastly abused.

There are certain rare instances in which a woman pregnant at term or beyond, cannot be made to go into labor. Her uterus will not respond to chemical or mechanical stimulation; uterine contractions do not occur. To dilate the cervix by the introduction of a succession of elastic bags and then do a version and accouchement forcé is now fortunately an obsolete procedure. It is brutal, fraught with grave danger to the fetus, and likely seriously to injure the mother. There is never an indication for great haste; the patient should be transported to a properly equipped operating room and abdominal Cæsarean section performed. Please do not

*Read by invitation as part of a symposium on the obstetric patient before the Yorkville Medical Society, April 17, 1916.

misunderstand me; I am not advocating Cæsarean section in every woman with weak uterine contractions; far from it. But in those fortunately rare cases where the uterus cannot be made to contract at the very onset of labor, when every known means to make it do so has failed—Cæsarean section and not accouchement forcé is the procedure indicated.

How shall we treat inertia in the first stage of labor—the cervix is not fully dilated, the pains are weak and ineffective, or even cease? If the patient has been many hours in labor, rest is the first essential, and a small dose of morphine followed by a few hours' sleep will often accomplish wonders. Chloral given by rectum has been recommended for this condition, but in my experience it has not proved nearly as effectual as morphine given hypodermically.

Of mechanical means to stimulate contractions at this stage, the best and safest is the introduction of the elastic bag into the cervix. The use of drugs is contraindicated. I am well aware of the "stunts" that are daily accomplished with pituitrin. Their perpetrators are even beginning to boast of them in the journals; but the stillbirths and the ruptured nteri are not so loudly acclaimed!

The mechanical rupture of the membrane is usually an efficient means of stimulating uterine contractions. It should not be attempted, however, before the cervix is fully dilated and the presenting part is engaged. Serious consequences are very apt to follow disregard of these conditions.

The disadvantages of a prolonged "dry" labor are too well known to necessitate comment. The dangers of rupturing the membrane before the presenting part is engaged are very real. I have seen, in consulting practice, prolapse of the cord, prolapse of an arm alongside the head, and face presentation in cases where the doctors ruptured the membranes early in labor to hasten matters and as they fondly hoped, to make things easy!

Inertia in the second stage of labor due to maternal weakness or exhaustion is a common condition met with in practice. It is here that pituituary extract has its legitimate field of usefulness. If the cervix is fully dilated, the head is well engaged in the pelvis, and there is no undue disproportion between the fetal head and the pelvis, one half to one c. c. of pituitrin may be given hypodermically; not to hasten a normally progressive labor, but when pains have ceased or have become very weak and ineffective. Chloroform must be kept ready for instant use should the contractions become excessively strong, or the head fails to advance. In this event the forceps, which should be ready for use before the pituitrin is injected, should be at once applied. The practitioner who would summarize for himself the use of pituitrin in labor, should look upon it as an efficient substitute for the low forceps operation.

Pituitrin may occasionally safely be employed as a *preliminary* to median forceps, but not as a substitute. That is to say, with the patient fully prepared for the forceps application and the anesthetist ready, a hypodermic injection of pituitrin is given; if with strong pains the head advances steadily, events may be awaited; if the head fails to advance, the patient should promptly be anesthetized and the forceps applied.

As to the dose of pituitrin—more than one c. c. should never be injected at one time; if at the end of half an hour or more there has been no result, or the contractions again weaken a second dose may be given. Very rarely should three doses be administered; if they fail, mechanical means of delivery should be resorted to.

PERSISTENT OCCIPUT POSTERIOR.

Never attempt to hasten labor by rupture of the membranes. If the head failed to engage, this would make it difficult or impossible to do a version which might become necessary. Dilatation of the cervix is best hastened by the introduction of the elastic bag. Before the head is engaged, it may be grasped with the whole hand, under full anesthesia, and an attempt made to rotate the occiput anteriorly. Pressure on the chin during pains favors flexion of the head and so aids rotation. When the head is firmly engaged and the progress of labor comes to a standstill, forceps are indicated. Pituitrin is contraindicated in persistent occiput posterior. If the forceps fail and the child is still alive, pubiotomy may, in selected cases, give the additional room necessary to bring the head through. It should rarely be resorted to. Cæsarean section can be considered only before rupture of the membranes, and when the aseptic conduct of labor has been perfect. Even under these circumstances the risk to the mother is smaller with a prophylactic version. When the child has died craniotomy is the operation of choice.

FACE PRESENTATION.

Forehead and brow presentations, unless corrected, terminate in face presentation. They may therefore be considered together. Preventable predisposing causes of this condition are a full bladder, full rectum, and artificial premature rupture of the membranes.

Before the head is engaged it may be possible to correct its position manually under anesthesia. The whole hand should be introduced for this procedure. If it succeeds, the hand should not be withdrawn, but the occiput should be held in place until uterine contractions have forced it into the pelvic inlet.

When the manual correction of the presentation is not possible, version should be done if conditions are right for it (membranes not too long ruptured, uterus not too firmly contracted).

Rarely labor will terminate spontaneously with a face presentation, but, unless the child is very small, with enormous damage to the maternal soft parts. With an impacted face, forceps may be attempted as a last resort before craniotomy. This is possible only when the chin rotates to the front. If the chin remains posterior, delivery of the whole head from below is impossible.

Pituitrin has no place in face presentation.

PROLAPSE OF THE CORD.

The fetal heart sounds and the pulsations of the cord should be carefully noted. If they are absent the child is dead and need not be considered. The most important point in the management of this condition is to discover it at the earliest possible

moment. Therefore every patient should be examined shortly after the rupture of the membranes.

As soon as the prolapse is discovered, the patient should be placed in the knee chest or Trendelenburg posture. If the cord does not slip back it should be replaced manually or by means of a loop of tape fastened to the end of any long instrument (bougie). If these attempts at replacement fail, version should be performed if the condition of the cervix and uterus permits. If the cord is prolapsed alongside the head and cannot be replaced, a quick delivery by forceps may be attempted.

PROLAPSE OF THE ARM ALONGSIDE OF THE HEAD.

Before rupture of the membranes, this should be treated by posture, the patient lying on the side opposite to that on which the limb is down, and with the pelvis elevated.

After rupture of the membranes, the arm should be replaced manually under anesthesia, and if it shows a tendency to come down again, held out of place until uterine contractions have brought about the engagement of the head. If manual replacement fails, version is the operation of choice.

After the head is engaged, prolapse of the arm should be treated either expectantly or by forceps, depending upon the progress of the labor.

BREECH PRESENTATION.

This might perhaps be included under the heading of normal labor, but complications are very apt to occur, and where they do not arise spontaneously "meddlesome midwifery" frequently brings them about. There is no reason why a labor with the child presenting by the breech should not terminate spontaneously, and it frequently does if the doctor will only give it a chance. The general principles which govern these cases can be summed up in the lately popular term, "watchful waiting."

Inertia uteri in the first stage should be treated on the principles already enunciated. In the second stage, with the breech well down in the pelvis, pituitrin may be tried for inertia, provided that all preparations have been made for a rapid manual extraction should it prove necessary.

If a foot has come down, it furnishes a ready means of traction; before this occurs one finger may be hooked into the groin and traction made by grasping the wrist of this hand with the other free hand until the thigh and leg have been sufficiently developed to make it feasible to grasp and bring down a foot.

In the normally progressing case the doctor should do nothing but await developments. One prime essential in these cases is a watch in plain sight of the obstetrician; if more than three minutes elapse between the birth of the umbilicus and the descent of the head into the vagina, interference may shortly become imperative to save the baby. These few minutes usually seem like as many hours, and unless the time is actually measured by a watch the temptation to seize the child and attempt extraction is too strong to be resisted. It is most desirable to await the descent of the arm below the pelvic brim, if at all feasible. If traction is made before this time, the complication of extended arms is almost inevitable.

If the arms have become extended, the posterior arm should be brought down first; the accoucheur's hand being passed up into the uterus along the hollow of the sacrum, the extended arm is swept downward by a maneuvre which has been aptly described as wiping the baby's face with its hand. This can usually be accomplished as soon as the bend of the elbow is reached. When the posterior arm has been brought down, the child should be rotated until the anterior arm lies posteriorly; it is then extracted similarly to its fellow. The extraction of the aftercoming head should proceed by the familiar method of Smellie-Veit. Moderate pressure by an assistant on the mother's abdomen just above the symphysis may aid materially at this stage. It is well to remember that the head may suddenly come through with a rush, and if the operator is not braced for this the perineum will be badly torn.

It should be reiterated that all this manipulation has no place in a normal breech case. The accoucheur should merely be prepared to extract the aftercoming head if it sticks too long. If things progress normally he has only to support the child's body, and with the descent of the head bring the fetal back forward over the mother's abdomen with one hand, while he supports the perineum with the other.

If the aftercoming head cannot be delivered by traction, an attempt may be made to deliver it with forceps, which should always be ready at hand in breech cases. Should this fail, the child will be dead, and it is far better technic to perforate and crush the aftercoming head than to force it through by brute strength.

Cæsarean section has recently been advocated for breech presentation in primiparæ. With a normal pelvis this procedure need only be mentioned to be condemned.

TRANSVERSE PRESENTATION.

Transverse presentation cannot be left to nature and always warrants interference. Early in labor external version should be attempted. Failing in this, with unruptured membranes and perfect asepsis having been maintained, Cæsarean section is the operation of choice in primiparæ. In multiparæ or in primiparæ not seen until after rupture of the membrane, version should be done when not contraindicated by the condition of the uterus.

The membranes are apt to rupture very early in labor; if so, dilatation of the cervix should be aided by the elastic bag as a preliminary to version.

In the neglected cases of transverse presentation, where version is no longer feasible, morcellement should be resorted to. Cæsarean section is too risky because of the danger of infection.

PLACENTA PRÆVIA.

Wherever possible it is highly desirable to deliver every case of placenta prævia in a well equipped operating room. In any event the physician should never leave the patient for a moment during labor, once the diagnosis is established.

The treatment must depend to a considerable extent upon whether the placenta is central, lateral, or marginal. The methods of treatment at our disposal are—gauze packing, insertion of an elastic bag, rupture of the membranes, version, and Cæsarean section.

In the simplest type of marginal placenta prævia, rupture of the membranes with the descending head acting as a tampon will prove all that is necessary to check the hemorrhage. Indeed some cases can be treated expectantly in the hope that the head will act in just this fashion without rupture of the membranes. Should bleeding become active, the membranes can at once be ruptured.

Gauze packing should be avoided, if at all possible. It predisposes to infection even with the most perfect technic. It may become imperative, however, if there is marked bleeding before dilatation of the cervix has occurred. Once the cervix is sufficiently opened, rupture of the membranes and insertion of the elastic bag is far preferable. This not only checks the bleeding, but helps to dilate the cervix and prepare for subsequent operative delivery should it become imperative.

After sufficient dilatation of the cervix, if the elastic bag does not control the hemorrhage until the head has come down, version with the pulling down of a leg to act as a compressor should be performed. Whether or not this should be followed by the immediate extraction of the child depends upon whether the hemorrhage has been checked or not. The policy of waiting for the natural forces to expel the child is much more favorable to its being born alive.

For central placenta prævia the operation of choice today is abdominal Cæsarean section; this applies especially to primiparæ and where the cervix is only slightly dilated. When section is not feasible, all the foregoing methods of procedure are applicable until the cervix is sufficiently dilated to perform a version. Once this stage of labor has been reached, the operator's hand must force its way right through the placenta, grasp a foot, and bring down a leg.

In the exigencies of general practice, version in placenta prævia will still give the best results for the mother.

Contemporary Comment

Social Insurance.—One of the important reports to the House of Delegates of the American Medical Association at Detroit, observes the *Journal of the Missouri State Medical Association* for August, 1916, was on social insurance. This report was largely statistical, and presented in a very comprehensive manner the workings of social insurance laws (or health insurance, as it is sometimes termed) as established in Germany and England, where the system has been in force and given satisfaction for several years. The report indicated that this method of dealing with health problems will soon become a general practice in this country, and therefore the medical profession should be prepared to adjust itself to the new conditions. A recent bulletin from the American Association for Labor Legislation says:

"In response to public interest in health insurance the Massachusetts legislature has created a commission to study social insurance with special reference to sickness. The State department of health and the bureau of statistics are directed to cooperate with the commission of nine members, which will prepare a report and recommend the form of legislation to be introduced in January, 1917. California has a similar State commission already at work on this problem, which is attracting wide attention since the introduction this year of bills for health insurance in Massachusetts, New York, and New Jersey. Proponents of this legislation believe it will bring about a movement for 'health first' comparable to the safety first campaign which followed workmen's compensation for accidents."

The American Association for Labor Legislation has given much study to health insurance, and has prepared a tentative bill for introduction in State legislatures, which represents the most recent measure that has been constructed for inaugurating health insurance as a State law.

The Sore Head.—It is plain to any one interested in the economic and social problems of medicine, remarks the *Buffalo Medical Journal* for August, 1916, that which is popularly termed sore headedness is a considerable and serious obstacle to professional unity, even to professional efficiency in its potential benefits to the community. If the sore head could be eliminated, the profession and the laity would both be immeasurably better off. But it is only fair to recognize that the sore head is, to some degree, a secondary evil. That is to say, his Ishmaelism is more or less justified by the existence of primary evils to which his own attitude is merely a natural reaction.

Once we commented on the difference between two brothers, one of whom had risen far beyond his original status but whose success was checked by his general reputation of being tricky and dishonest, while the other, though in humble circumstances, seemed to be perfectly upright. "Bless you," was the reply, "——— (the second brother) is eating his heart out because he does not know enough to be as much of a shyster as ——— (the former)." This is the trouble with many sore heads. It is not so much the existence of an ethical evil that troubles them as the fact that they are the victims and not the perpetrators of it.

We have heard of a physician, by no means a sore head, who, toward the close of an active independent career, very successful, too, expressed the regret that, instead of becoming known as one who would always protest fearlessly against an evil however prominent its source, he had not acquiesced and thus gained friendship and prestige from the very sources that he had antagonized. Such regret is itself regrettable. The sore head is not only a general nuisance, but he damages his own cause most of all. The essential trouble with him is his personal bias. He is thinking too much of the effect of general conditions on himself, too much of the individual source from which such conditions emanate. If he will think in terms of all who are injured; if he will act without malice to any one but against wrong conditions in general, he will cease to be a sore head and will exert a real influence toward reform.

THE UNUSUAL.

There has been much ado, there has been much running to and fro, much offering of prizes for miraculous cures developed on short notice, and much newspaper and other talk over the alleged presence of an epidemic of anterior poliomyelitis. It is quite right that there should be active agitation over this disease, but the only reason that there is this unusual stir, is that infantile paralysis is uncommon, and that its epidemics are, for this country, comparatively new. We have had diphtheria and measles and scarlet fever with us for a long time, and yet, we believe, no large prizes have been offered for their cure, no specialists have been hurried to the scene of the epidemic to see what could be done to check its spread, and the national government has never had a hand in its suppression. Even local authorities have seldom taken the trouble to clean up on a large scale in order to check an epidemic of these diseases. Yet the death toll from diphtheria is still approximately 25,000 for the United States each year, the mortality from scarlet fever is six times that from anterior poliomyelitis, while its annual incidence in all our cities usually far surpasses that of the worst outbreaks of the more unusual malady. Even tuberculosis, about which there was a wave of excitement some time ago, is fairly holding its own with a death rate reduced only from 201 to 147. Infantile paralysis is always present in the community, but it leaves a large percentage of cripples in its wake, and so seems the more dreadful. Doubtless this has something to do with our fear of it, but the crippling from scarlet fever alone, the impaired hearing, damaged kidneys, and heart defects, if not so evident, is more serious than an abbreviated and weakened limb, and the army of scarlet fever cripples is larger than we realize. The same is true of measles, diphtheria, whooping cough, typhoid, and malaria.

We become attached to old acquaintances, especially those that were once believed to have been sent for our chastisement and the correction of our evil ways, and perhaps, after all, we like to have the plagues (no one calls *them* such) of the good old infections with us. At any rate, no one is making any great fuss about them commensurate with that which is being made over this less common and less destructive disease. We are reminded of the incident related by an African explorer looking for sport with big game. A native, finding he was interested in crocodiles, told him that at a nearby village he could get, without difficulty, a shot at a fine specimen. The hunter expressed much skepticism over the presence of a beast of the kind described so near to human habitation, but, being further assured by the man, he followed his guidance, and, close by the village, he found an enormous beast grown obese and lying, lazy or satisfied, on the bank of the stream. He had no difficulty in dispatching it with a bullet, to the evident satisfaction of the natives, who told him that for some years he had made his meals on unwary children or adults of the village. To the hunter's wondering inquiry why they had allowed him thus to prey upon them for so long they replied, "Oh, powder and lead are very expensive, and we are a poor people."

In our attitude toward the familiar diseases which take enormous toll of innocent children and adults we are very like the people of this poor African village. Our dollars and cents seem very precious and we use them for other purposes than health protection. We cannot, or at any rate do not, afford even a national department of health, though we do have a department much devoted to the health of plants and animals. We often have no local health departments, and where we have them they are usually badly hampered for lack of both funds and moral support. We are as obtuse as the Africans as

to the economy of interference with disease. If popular agitation over the presence of anterior poliomyelitis could only help to open the eyes of the public to the more disastrous but more familiar sources of untimely injury and death—to our other annual disease plagues—we might even be thankful for its prevalence during the past two months.

PATIENCE IN THE TREATMENT OF POLIOMYELITIS.

Much of our treatment of the weakness and deformity which may result from poliomyelitis fails owing to the lack of proper following up. This is the opinion of Dr. Francis Hernaman-Johnson, who communicates to the *Lancet* for July 29, 1916, the results he obtained in a little girl whom he saw for the first time in 1911. He gives the following details concerning the patient's condition at that time:

The patient, a girl aged five years, suffered from infantile paralysis of the right lower limb. The attack had occurred at the age of eighteen months. The child was wearing an appliance weighing six pounds, the main feature of which was a heavy steel running up the leg from ankle to waist and secured round the latter by a metal band. The patient progressed by a curious hopping motion, dragging the affected limb behind her, with the foot everted almost to a right angle. The limb had shown no improvement for two years. On examination all the muscles below the knee were found to be completely paralyzed, so that the condition known as "flail ankle" obtained. The thigh and buttock muscles were small and weakly, but they responded fairly well to faradic stimulation. Partial subluxation of the knee joint was also present, partly due to the lack of tone in the biceps and quadriceps femoris, but chiefly depending on the complete failure of the gastrocnemius. The whole limb was shrunken, and showed two and one half inches of relative shortening. It was, moreover, cold and clammy to the touch, with a temperature 2° F., below that of its fellow, a condition judged to be in part due to the weight and rigidity of its supporting apparatus. As is frequently the case in such limbs, sensibility to pain and changes of temperature was greatly diminished, although tactile sensation remained unaffected. A careful electrical investigation led the examiner to conclude that the leg muscles were probably hopeless, but the parents were told that the child could do without external irons and need wear no support of any kind above the middle of the thigh.

A special boot was constructed, weighing only two pounds, in which light steel supports were concealed. Under treatment by electrical stimulation a very rapid increase in size and power occurred in the buttock and thigh muscles. At the end of two months—when the treatment was suspended—there was not, however, any sign of improvement below the knee.

The child has been seen twice yearly until recently and has had about a month's electrical treatment on each occasion. At the end of two years Doctor Hernaman-Johnson was surprised to find that power was beginning to return in the calf muscles and the "relative shortening" had decreased from two and a half to one and a half inch. He took away some of the support from the knee, and a year later removed it all. Early in 1915, four years after the patient was first examined, some amount of control on the ankle joint had been regained, and the affected limb is now only one inch shorter than its fellow. The child now wears an ordinary boot with a little leather stiffening, and an internal raised sole. The curve of the leg has become normal, and the size and density of the bones have increased. In a favorable case, the relative shortening of the limb should grow less year by year, and therefore any boot extension must be altered accordingly.

Doctor Hernaman-Johnson offers three rules which are always to be kept in mind: 1. A muscle which is chronically overstretched cannot recover. It must be relaxed by means of a suitable splint. 2. When such a muscle responds moderately well to Faradism, recovery will be greatly hastened by daily rhythmical electrical stimulation. The relaxed position must, however, be maintained throughout. 3. Exercise, whether voluntary or electrically provoked, must never be carried to the point of fatigue. The contraction of a muscle should be not less vigorous—with the same stimulus—at the end of a sitting than at its beginning. It is better that recovery should be delayed by overcaution than that it should be made impossible by excess of zeal.

ABUSE OF THE SALINE SOLUTION.

There has sprung up an indiscriminate use of saline solution, especially the normal salt solution, both intravenously and by enteroclysis, in the belief that it had extraordinary therapeutic qualities in shock following operations, in nephritis as a flushing medium, and in anemia following severe hemorrhages, in the latter instance to replace the actual amount of fluid lost in the hemorrhage. In the disturbance of the normal inorganic balance of the system by the introduction of sodium chloride solution the kidneys must abandon elimination of organic acids and the toxins to take care of the salt introduced, in order to restore balance. In toxemias, therefore, it may be seen that the introduction of salt solution may be a positive hindrance to elimination by the kidney of the very toxins or acids that the salt solution is intended to help eliminate. In relieving postoperative thirst Trout found that ordinary hydrant water was far more efficacious and that more water was actually absorbed when given by enteroclysis than if salt solution was used by the same method. On the other hand, in true operative shock in which there is vasomotor paralysis, and overfilling of the splanchnic vessels, and an acute dilatation of the right heart, the addition of normal

salt solution to the afferent vessels may be of immediate disastrous effect.

In the secondary anemias with low hemoglobin content the addition of large amounts of normal salt solution is often just enough to dilute the blood and reduce the hemoglobin below vital requirements. A patient who is otherwise slowly recovering, and in whom hemoglobin is slowly increasing, is often put beyond the possibility of recovery by this useless reduction of the hemoglobin. The flushing of the kidneys in nephritis with normal salt solution, where the urine is already highly charged with sodium chloride, decreases proper elimination of water and causes the retention edema common in nephritic conditions. Moreover, the addition of an isotonic or of a hypertonic salt solution to blood that is already hypertonic, results in grave evidences of high blood pressure.

McKelvy found that where it was desired to flush the kidneys in toxemias or otherwise, or to reduce acidosis if that seems to be the greatest danger, the use of a ten or fifteen per cent. glucose solution was not irritating to the kidneys, nor toxic or harmful in any way. The kidneys were not taxed to eliminate it nor was there an inorganic disturbance of balance to restore it. In fact, in acidosis this solution acted better than the sodium chloride.

Finally, it is to be remembered that in using this form of hydrotherapeutics, introduction of saline solution into the circulation, directly or indirectly, may embarrass an already overfilled right heart; too much salt solution may overtax an already weakened or otherwise engaged kidney; and it may act to reduce an already insufficient hemoglobin. Thus the use of saline infusions is often contraindicated in conditions of high blood pressure, acidosis, low hemoglobin content, and often in postoperative shock.

SLEEP.

In a recent number of the *New York Times* there was published a pathetic open letter "written by one who tried to play Edison's game of much work and little sleep, and who has lost his health in the process." Doubtless, from an early time the foolishly ambitious have tried to get along with less sleep than nature requires, and the curious public (curious subjectively and objectively) is always more interested in the freakish doings of the few than in the sensible conduct of the average human being. They are little impressed with the miracle of everyday life. Mr. Edison, being a scientist, must needs be a good example of correct sleeping habits, but, alas, when it comes to caring for his body a scientist is often more of a fool than his less learned fellow mortal. We do not know how much sleep Mr. Edison requires or takes, but we are informed that he is far from being in the most enviable state of health. We do know, that most great men have needed more sleep and have taken more than has been credited to them. In one of our standard works on therapeutics the writer states that Napoleon took but four hours of sleep. Had the writer been as careful in his research in this matter as in others he would have found that Napoleon, who was blessed, if ever man was, "with the constitution of an ox," took between six and eight hours of sleep, and though he could go for long intervals without rest, always made up for such loss, on one occasion sleeping for thirty-six hours at a stretch. Benjamin Franklin, who was as thrifty of his time as he dared to be, and who was very robust, limited himself to six hours of repose but not less, and if the history of the robust great were looked into carefully it would be found that they had about as much sleep as the average man, and certainly few of them were foolish enough to try to get along with less than they craved. If one desires a commentary on the woes of sleeplessness he has but to read the autobiography of Herbert Spencer.

It is a greater gift to be able to sleep "at will" and under any circumstances than to do with little sleep. More time is wasted in getting to sleep than in sleeping. On the other hand, there is little doubt that too long sleep, too protracted bodily relaxation, is not best for the human organism, and many of our relaxed young people, with no regular employment and more time than they know how to consume to advantage, would be better for spending less time in bed. A prescription for early rising would do them good. The physician needs as much sleep as the next person, and when he is robbed of it, ought to make it a point to have his nap to make up for it. Only so can he expect to be abundantly awake at his work and to keep going for the allotted span of years of labor.

A SIMPLE DEVICE FOR THE DISINFECTION OF DEEP SINUSES.

When he first had under his care in the Red Cross hospital cases with septic sinuses Dr. F. de Coverley Veale, of Mumbles, England, experienced difficulty in getting any disinfectant into them so as to reach to the deeper parts. He then asked a large Bristol manufacturing concern to make a German silver cannula to fit a hypodermic syringe. This has been a most successful method of washing the sinuses with hydrogen peroxide or any other solution in small quantity, and appears to hasten healing very materially; liquor alantoininæ has also been used in this way with success. The cannula can be bent in any way required, and the blunt end prevents it doing harm to the tissues. Three inches is a convenient length for the cannula, according to the deviser's statement in the *British Medical Journal* for July 8, 1916.

HAY FEVER AND ITS PREVENTION.

This is the season when that troublesome complaint, hay fever, is prevalent. Undoubtedly there are certain persons who have an idiosyncrasy for the affection, and as soon as the time arrives when the pollen is in seed, all the disagreeable symptoms which are the features of the disorder are in full sway. In *Public Health Reports,* July 21, 1916, Dr. W. Scheppergrell writes concerning hay fever. There are many weeds which are responsible for hay fever, and it should be borne in mind that the grasses are also on the hay fever list. It is probable, too, that the majority of weeds which are found in great profusion and the pollen of which is abundant and wind-borne, are the cause of hay fever to some persons. It has been found that in most parts of the United States from one to two per cent. of the population suffer from hay fever at some portion of the year, indicating that its victims may be counted by scores of thousands. Scheppergrell states that the question of susceptibility is complicated, but in this respect does not differ materially from susceptibility in other diseases. Hay fever is common in children, but the reason that it is not more generally detected is because such attacks are usually mistaken for "colds."

With regard to treatment, thus far no method has given satisfactory results. So far as prevention is concerned, the means toward the attainment of this object are much more evident. The first most important step in this direction is the education of the public in the responsibility of pollens of weeds in causing hay fever. When the public realizes that the common weeds are the cause of suffering to many persons who may be living at a considerable distance, it will view these weeds from a new angle and will make use of one of the many ways of destroying them, or at least preventing them from reaching the stage of pollination. Scheppergrell is of the opinion that legislation can accomplish much in the way of prevention of hay fever. In fact, many States have enacted laws to control the growth of weeds with a very large measure of success. Of course, in order that uniform and complete results should follow the enactment of any laws it will be necessary for legislation to be brought forward for the control of hay fever weeds in the various States.

Obituary

JOHN BENJAMIN MURPHY, M. D.,

of Chicago, Ill.

The medical profession has met with a serious loss in the death of John Benjamin Murphy, one of the world's greatest surgeons, who died suddenly on August 11, 1916, at Mackinac Island. Dr. Murphy had been in poor health for many months, suffering from heart disease. He was born in Appleton, Wisconsin, on December 21, 1857. He received his early education in the High School of Appleton and was graduated from Rush Medical College, Chicago, in 1879. After three years of practice he went to Germany, where he studied for two years, and returning to Chicago soon became a leader, especially in abdominal and bone surgery. He was the head of the department of surgery and clinical surgery in Northwestern University Medical School, and had been professor of clinical surgery in the Chicago Post Graduate Medical School since 1895. He was also consulting surgeon to the Cook County and Alexian Brothers hospitals Much of his best work was done as chief surgeon to Mercy Hospital, and it was here that he devised many of his most successful and unusual operations. He was also attending surgeon to the West Side Hospital, and in 1898 became first lieutenant in the Medical Reserve Corps of the United States army.

THE LATE DR. JOHN B. MURPHY.

In 1899, in Chicago, he devised a small metal ball, now known as the Murphy button, for uniting severed intestines, a device which did much to revolutionize methods of intestinal surgery. As early as 1892, in New York, Doctor Murphy had successfully used this button in a case of gangrene of the intestines. In 1898 he advocated the practice of inducing artificial pneumothorax by compression of the affected lungs with nitrogen, a procedure of acknowledged value. His success in grafting cartilage and replacing bone tissue, in the estimation of the laity, was little less than miraculous.

In 1911 he received the honor of election as president of the American Medical Association; in 1902 he received the Lætare medal from the University of Notre Dame, and in 1908 was granted the degree of Master of Science by the University of Sheffield,

England. His talents were recognized freely by surgeons abroad as well as in the United States. He was a fellow of the American Surgical Association; life member of the Deutsche Gesellschaft für Chirurgie, Berlin; the Société Chirurgicale, Paris, and many of the leading medical societies of Illinois and the Middle West. When Colonel Roosevelt was shot in Chicago, October, 1912, Dr. Murphy was called to take charge of the case. On June 16, 1916, Dr. Murphy received the collar and cross of the Order of Saint Gregory the Great. In his inaugural address as president of the American Medical Association, in 1911, Dr. Murphy not only advocated the highest standards of medical education, but also expressed himself strongly in favor of popular medical instruction through competent medical contributions to the lay press. He had been a frequent and valued contributor to the NEW YORK MEDICAL JOURNAL.

News Items

Johns Hopkins Hospital Abandons Twilight Sleep.—After more than a year's use of the twilight sleep method in childbirth, the obstetricians of Johns Hopkins Hospital have discontinued its use. They concluded that the method was too dangerous and the menace to the life of the child too grave. They found that it could be used with safety only under exceptional circumstances and with the most skilful supervision.

A Directory of Health Authorities.—A directory of the State and insular health authorities of the United States has been compiled by the United States Public Health Service which will be of value to all health officers and others interested in public health activities. The pamphlet is Reprint No. 344 from the *Public Health Reports*, and may be obtained from the superintendent of documents, Government Printing Office, Washington, D. C., at five cents a copy.

Personal.—Dr. Albert Warren Ferris, formerly medical expert and superintending director for the Commissioners of the State Reservation at Saratoga Springs, has gone into practice in that city. The commission was abolished and there is no physician now connected with the State control of the mineral springs or bath houses.

Dr. Isham G. Harris, formerly superintendent of the Mohansic State Hospital, has been appointed superintendent of the Brooklyn State Hospital, to succeed Dr. Elbert M. Somers, who resigned recently on account of ill health and severed his connection with the institution on August 1st.

American Public Health Association.—The forty-fourth annual meeting of this association will be held in Cincinnati, October 24th to 27th, under the presidency of Dr. John F. Anderson, of New Brunswick, N. J., formerly assistant surgeon general of the United States Public Health Service. The official headquarters of the association will be at the Hotel Sinton, and the general sessions will be held at the Hotel Gibson. The association is divided into the following sections, each of which has arranged an interesting program: Public health administration, laboratory, sanitary engineering, vital statistics, sociology, and industrial hygiene. A preliminary program of the meeting has been issued which shows that in addition to the reading and discussion of papers on topics relating to special phases of public health work an elaborate program of entertainments has been prepared by the local executive committee, of which Dr. J. H. Landis is chairman, Dr. William H. Peters is secretary and treasurer, and Dr. E. O. Smith a member. For full information regarding the meeting, address the American Public Health Association, 755 Boylston Street, Boston, Mass.

A Symposium on Occupational Diseases.—At a meeting of the American Chemical Society, to be held in New York, September 25th to 30th, the program will include a symposium on occupational diseases which will be presided over by Professor Charles Baskerville, head of the department of chemistry of the College of the City of New York. Among the topics which will be discussed are the chemical trades, prophylaxis in chemical industry, diseases incidental to work in aniline and other coal tar products, cedar lumber, mines, and explosives. There will be a general discussion by leading authorities of the country, among them being Dr. W. Gilman Thompson, of New York, Dr. F. L. Hofman, Dr. J. W. Schereschewsky, G. P. Adamson, H. K. Benson, W. A. Lynott, Alice Hamilton, and J. B. Andrews.

Army Medical Corps Examinations.—The surgeon general of the army announces that preliminary examinations for appointment of first lieutenants in the Army Medical Corps will be held on September 5, 1916, at points to be hereafter designated. Full information concerning these examinations can be procured upon application to the Surgeon General, United States Army, Washington, D. C. The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty-two years of age, a graduate of a medical school legally authorized to confer the degree of Doctor of Medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training as an intern after graduation. In order to perfect all necessary arrangements for the examinations, applications should be forwarded at once to the Adjutant General of the Army. There are at present over 200 vacancies in the Medical Corps of the Army.

A Special Infantile Paralysis Number of Health News.—Commissioner Hermann M. Biggs, of the New York State Department of Health, has devoted the entire August issue of *Health News* to the subject of infantile paralysis. Dr. Simon Flexner, director of laboratories in the Rockefeller Institute for Medical Research, contributed the leading article, in which he presents a summary of what is known about the disease. The treatment of infantile paralysis, with especial reference to the earlier stages, is taken up by Dr. Robert W. Lovett, of Harvard University and the Children's Hospital of Boston. Doctor Lovett writes at some length on various aspects of the disease and describes the courses of treatment for the acute, convalescent, and chronic stages. Doctor Biggs, in an article regarding the epidemic, notes that the control of the disease becomes most difficult because it is not easy to make an accurate diagnosis. He expresses his appreciation of the support which he has received not alone from the administrative staff of the State Department and the local health officers, but also from private physicians, railroad officials, and the press throughout the State.

The Poliomyleitis Epidemic.—According to the health department, 133 new cases of infantile paralysis were reported in the city of New York on August 16th, with 34 deaths. The total number of cases reported up to that date was 6,653, with 1,497 deaths. Of the total number of cases, 3,480 were treated in hospitals, 2,305 patients receiving treatment in the hospitals of the department, 525 in other city hospitals, 591 in private hospitals, and 59 at Swinburne Island. Up to and including August 2d, a total of 336 cases were reported in New York State, exclusive of New York City. Fifty additional cases outside of New York City were reported to the State Department of Health for the twenty-four hours ending at 5 p. m., August 15th. The immigration laws have been suspended in order to permit the entry of nurses from Canada who have been engaged by the Health Department. September 25th has been set as the earliest date at which the public schools of the city will be opened with the understanding that this date may be further postponed and that two weeks' notice of the opening of the schools will be given by the authorities. Health authorities from thirty-eight States met in Washington on August 17th to exchange views on the disease with the Public Health Service and others who had been invited by Surgeon General Blue to attend this conference.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirty-third Communication.

INFLUENZA.

In the absence of any specific treatment for influenza, little else can be done medicinally other than to make the patient less uncomfortable, and to offset adverse symptoms. Usually in this illness certain definite symptoms are present, such as severe headache and lumbar neuralgia, considerable prostration, and bronchitis, and not infrequently, complications of the heart, lungs, and nervous system. Meeting these various symptoms as they arise is the physician's main duty.

The pains of the head and back seem to be due largely to localized congestion of the meninges and neural sheaths, and do not seem amenable to medicines; at present, therefore, we must have recourse to those drugs which either dull the perception of pain, as opium, or interrupt at some point the transmission of pain impulses, as acetphenetidin.

Sometimes the use, at the onset of the disease, of a large dose, 0.5 gram, of Dover's powder, taken with a small dose, 0.06 gram, of acetphenetidin, together with copious libations of a hot innocent drink, like weak tea, will either apparently abort mild cases or else, in severe attacks, carry the patient more comfortably through the earlier myalgic stages. The combination here suggested serves to lessen perception of pain, causes a dilatation of the cutaneous bloodvessels with accompanying augmentation of hidrosis, and to some extent may increase hemic metabolism.

Quinine has been advised for the neuralgic pains, but unless quinine has a selective germicidal action on the influenza bacillus it is difficult to see wherein quinine would alleviate the pain at all. One writer has made this curious statement: "It (quinine) not only serves to reduce the temperature, but also to sustain the vital forces, to control the nervous symptoms, and lessen the tendency to inflammatory reactions." Quinine may be an indifferent antipyretic, but the other statements concerning the alleged value of quinine must be deemed insufficiently considered. Quinine is a protoplasmic poison, it diminishes the number of leucocytes, destroys some of the erythrocytes, produces degenerative changes in both optic and auditory nerves, irritates the alimentary tract and glands, and interferes more or less with cellular metabolism throughout the body. The evidence of pharmacodynamics does not support the use of quinine in influenza.

The prostration, being largely due to accumulating bacteriotoxins, may be relieved to some extent by a flushing of the alimentary tract, and by a washing of the blood stream through drinking liberally of hot beverages or by taking warm saline enemata. One writer advocates the administration of a grain of calomel every three or four hours for a day or more, but the severe purging and marked tenesmus which this would frequently cause, besides the ever present possibility of mercurial poisoning, make such heroic treatment inadvisable. It is not duodenal irritation that is needed, but a clearing of the bowel and the temporary establishment therein of a considerable exosmosis; for this purpose, a saline is of better service than calomel.

The mental depression and occasional sleeplessness are best treated by cool spongings and the ice cap, with complete rest and quiet during the sponging intervals.

Remedies for the treatment of the attendant bronchitis are not satisfactory. Codeine, by lessening the perception of trachial irritation, often reduces the frequency of a too harassing cough. Ammonium chloride, in the form of nascent vapor, may have some helpful influence in promoting ease of coughing, if we accept the assertion that this chloride promotes fluidity of mucous secretion.

For the coryza a recent text states: "Inunctions of animal fats over the forehead and bridge of the nose are useful." One can but wonder why a vegetable fat would not be equally efficient. The massage, by counter irritation, or a possible reflex, might help a little, but any peculiar potency existing in the animal fat simply applied requires explanation. This belief used to be commonly held by mountain grandams, but is rarely promulgated nowadays by college teachers.

The complications are to be met by suitable drugs or measures. Threatened heart failure is to be parried with known cardiac controllers; excessive nervous manifestations may be controlled by the cautious use of opiates, sometimes supplemented by the cord irritant, strychnine. Rheumatoid symptoms indicate need for further stimulation of the several emunctories.

Autoserobacterine.—Michael G. Wohl (*American Journal of the Medical Sciences*, August, 1916) gives the following technic for the preparation of autosensitized vaccines: 1. A pure culture is obtained from the lesion on solid medium. Three ordinary culture tubes are sufficient. 2. To each tube one c. c. of sterile normal salt solution is added. Shake the fluid so as to bring the microorganisms into suspension. To facilitate the washing off of the bacteria use a platinum loop. 3. Transfer the bacterial emulsion into a sterile tube to which sterile glass beads are added to break up the clumps. 4. The bacterial emulsion is standardized by Wright's method of counting the proportion of red corpuscles and bacteria in the unit of equal parts of blood and bacterial emulsion, and proper dilutions are prepared. 5. The vaccines are now sterilized in a water bath at 56° to 58° C. for thirty to forty-five minutes. 6. Blood is obtained from the patient from a

prominent vein at the elbow, five to ten c. c., under strict asepsis, placed in a cold place for three hours, and serum pipetted off. 7. Inactivate the serum at 56° C. for half an hour. 8. Add from one to three c. c. of the inactivated serum to vaccine No. 1, and No. 2, if enough serum is obtained, and place in incubator at 37° C. for six hours. For subsequent doses obtain more blood. 9. Culture vaccine to test its sterility and if it is found sterile, administer it hypodermically.

Specific Treatment of Infantile Paralysis.—Abraham Sophian (*Jour. A. M. A.*, Aug. 5, 1916) considers the treatment of the acute stage of infantile paralysis under the following topics: The relief of hydrocephalus; the intraspinal injection of sera; control of special symptoms; general symptomatic treatment; and the orthopedic treatment. In a large number of the cases of this disease in their most acute stages there will be symptoms of cerebral or medullary disturbance which is almost always due chiefly to the presence of hydrocephalus. This is the usual cause of respiratory embarrassment or failure. For this condition the most imperative treatment is the removal of spinal fluid through lumbar puncture. The fluid may safely be removed until the pressure falls to normal and the procedure may be repeated whenever there is a return of symptoms of pressure. It has been shown in the case of other meningeal diseases that the injection into the spinal dura of normal serum provokes a prompt and marked hyperleucocytosis with polynuclear cells greatly predominating. This is not a specific reaction, but one merely due to the introduction of a foreign protein. This hyperleucocytosis should theoretically be of considerable value in promoting recovery in poliomyelitis. A small number of cases have been treated with such injections and the indication seems to be that the injection of normal serum—horse or human—will prove of considerable value. At least the measure is entirely devoid of danger and it should be given a thorough trial before rejection or definite adoption. In a small series of cases serum from convalescent human cases of the disease was injected intraspinally, but the results were apparently no better than those obtained from the use of normal non-immune serum.

A Plan of Treatment in Infantile Paralysis.—Robert W. Lovett (*Jour. A. M. A.*, Aug. 5, 1916) affirms that during the first stage, which lasts to the disappearance of all tenderness or from one to three months, the essential requirement of treatment is absolute rest and the prevention of deformity. No serum, drug, or proceeding is known to abort the disease or prevent the paralysis. Near the end of this period the immersion of the affected parts in a warm salt bath permits some exercise and is beneficial. The second stage lasts from the end of the first for two or more years, after which the disease may be regarded as having become more or less stationary. In this stage the main consideration is the condition of the muscles, which are far more commonly weakened rather than totally paralyzed. The ambulatory treatment with careful avoidance of fatigue and deformity is best during this period. Braces or splints should be used only while the patient is actually on his feet and their only purpose is to correct deformity and prevent the stretching of greatly weakened muscles. It may be necessary to institute regular methods of reeducation to teach the patient to walk. Combined with the ambulatory treatment, measures designed to influence the muscles favorably should be employed. Massage is helpful if used in moderation, and if it is borne in mind that its value is only local in the improvement of the circulation in the manipulated muscles. It is likely to be harmful if used violently or for too long a time. No form of electrical stimulation seems to be of any value, and much harm has been done by the use of strong currents. The use of local heat in the form of electric light baths or hot ovens is of aid in improving the circulation in the muscles and the conditions for their contraction. The most important and valuable measure of all, however, in this stage is that of muscle training, which should be carried out by an experienced person under the constant guidance of the physician and controlled by careful determinations of the degree of gain in muscular strength. If there is any type of fixed deformity it must be corrected before any treatment is undertaken, in order to secure good results. In any case fatigue and overtreatment by massage or exercise must be most sedulously avoided, which may be accomplished by frequent measurements of the power of the various muscles before and after treatment. The indications for treatment in the third stage are to continue the plan adopted in the second stage, and to resort to some one or more of the suitable operations for the correction of deformity and the improvement of function, such as tendon transplantation, etc.

Treatment of Hay Fever.—P. Bonnier (*Bulletin de l'Académie de médecine,* June 27, 1916) asserts that no neurotic disorder is more readily and promptly curable than hay fever. The affection is one involving the defensive centres of the respiratory passages in the medulla, the sensory fibres originating in the vicinity of these centres projecting the irritation of the latter in the form of intolerable pruriginous impressions in the vertex, eyes, nose, palate, ears, larynx, chin, etc. In the mucous surfaces exposed to the contact of irritating particles, such as train dust, pollen, and odoriferous material, the itching becomes particularly violent and, in its turn, keeps up the central irritation. To check the attack and break up the neurosis, restoration of these centres to their normal type of activity through a forcible physiological impression is all that is required. The point of intranasal itching, often precisely located by the patient, affords direct communication with the centres which are to receive this impression. By testing the sensitiveness of the anterior nasal mucosa with the tip of a fine galvanocautery, without preliminary local anesthesia, a point will easily be found at which the least contact will cause the patient to flinch and induce immediate congestion of the conjunctiva and lacrymation. At this point a slight, hardly perceptible cauterization should be carried out. This startles, without irritating, the centres under treatment, and the effect on the mucosa persists long enough to allow these centres to

regain their functional equilibrium. After a perfunctory paroxysm the patient is, in twenty-five per cent. of the cases, at once freed from his ailment. In the remainder, several treatments are required. Persistently rebellious cases are the exception, and the procedure, as a rule, not only checks the hay fever attack in that season, but removes predisposition to the disease, which fails to reappear in the following year. This form of treatment has been applied by the author for twenty years, with unvarying, favorable results.

Corsets versus Backache and Fatigue.—Alice S. Cutler (*Boston Medical and Surgical Journal*, August 3, 1916) urges that more attention be paid to the corsets worn by women, as she finds this to be a matter into which the family physician is not accustomed to inquire. For the past two years she has been experimenting with corsets on patients, nurses, and friends, and has found that much relief may be obtained by wearing front laced corsets, instead of those that lace in the back. They should be put on while the patient is lying on her back with her buttocks supported by a pillow. Her own personal experience is the same as that of over four hundred women, that she does not become fatigued by work so easily and feels better when she wears a front laced corset.

Indications and Contraindications for Pneumothorax.—Clive Riviere (*Lancet*, July 15, 1916) finds that the most strikingly beneficial results are to be obtained from pneumothorax in that group with clinically unilateral pulmonary tuberculosis with advanced lesions, including fibrosis and cavitation, but with little evidence of marked activity. Though clinically unilateral, x ray examination will show marked peribronchial tuberculosis radiating from the hilus. So long, however, as there is no clinical evidence of tuberculosis in the second lung, pneumothorax may be used with great benefit. Even the disease in the better lung usually markedly improves under this treatment. In apical tuberculosis pneumothorax is usually contraindicated unless the process is restricted to one lung or unless the disease in the other lung is extremely early and slight. Further, such cases of early phthisis are the most amenable of all to the other methods of treatment commonly employed. Where there is diabetes, kidney disease, or circulatory complications, pneumothorax is also contraindicated. Unless very far advanced laryngeal tuberculosis is not a contraindication. The occurrence of hemoptysis is almost always an imperative indication for the use of pneumothorax.

Prophylaxis of Cerebrospinal Meningitis, Grippe, Eruptive Fevers, and Mumps by Vincent's Method.—Lefas (*Presse médicale*, June 29, 1916) strongly recommends the measures suggested by Vincent and recently successfully applied by Coulomb in military practice in the prevention of epidemic meningitis, grip, sore throat, etc., i. e., of affections developing in the nasopharynx or oral cavity or in which these parts serve as portal of entry. Six hundred young soldiers were ordered to wash out the mouth and gargle with Lugol's solution or with a five per cent. dilution of Labarraque's solution (Liquor sodæ chlorinatæ, U. S. P.). As a result, the number of cases of angina or pharyngitis markedly diminished, immediately increasing threefold when the procedure was discontinued for a week, and promptly dropping to nil when it was resumed. Meningitis then appearing in epidemic form, the occupants of the rooms in which the disease occurred were isolated and ordered to gargle with dilute hydrogen dioxide solution and practise antiseptic inhalations. No results being thus obtained, more comprehensive measures were taken. The entire force of 600 men was kept in the barracks for four or five days. Gargling and mouth washing with hydrogen dioxide, diluted one in ten, three times a day after meals, was ordered. The tonsils and pharynx of each man were carefully painted with iodized glycerin:

℞ Iodi, ... } ..... āā 10 grams;
Potassii iodidi, .. }
Glycerini, ... 300 grams.
Fiat solutio.

Inhalation of fumes of the following preparation, slowly and through each nostril, three times a day for two minutes, was likewise practised:

℞ Iodi, ... 20 grams;
Guaiacolis, ... 2 grams;
Thymolis, ... 0.25 gram;
Alcoholis (60 per cent.), ... 200 grams.
Misce.

The fumes were inhaled from small cups partly immersed in hot water. Two days after the beginning of these measures, no new cases of meningitis developed, though previously one new case had developed every day. The disease manifesting again later, through infection from the outside, the prophylactic measures were applied in 107 isolated suspects, fifteen of which were meningococcus carriers. After four days of treatment and two subsequent days without treatment meningococci had disappeared from the nasopharyngeal secretions of the carriers, and no additional case of meningitis developed. The measures referred to also caused progressive disappearance, within a few days, of latent rhinitis and rhinopharyngitis to which a large number of the men were subject. Prophylactic application of the procedure, including isolation and local medication for four days, is suggested not only in cerebrospinal meningitis, but in the various eruptive fevers and in mumps.

How Labor May Be Made More Comfortable.—Greer Baughman (*American Journal of Obstetrics*, April, 1916) asserts that the pregnant woman who is doing well has an increase of the thyroid secretion, which renders her more sensitive to pain than the nonpregnant subject. One method of making the patient more comfortable is to gain her perfect confidence, through frequent visits to the office, correction of her minor ailments, and general encouragement. One need not limit one's endeavors, however, to this plan alone. "Twilight sleep" should be suggested only to those women who are extremely nervous and abnormally apprehensive and in whom the resulting delay of two hours is not likely to make a serious difference in the chances of the baby or mother. It should be applied, moreover, only where both the woman and her husband have been enabled to weigh its advantages and disadvantages and have decided that they want it tried. In

other cases it is inadvisable to apply any quieting measure save moral suasion until the cervix has begun to thin out well and is about the size of a silver quarter. After an effectual soapsuds enema twenty grains of chloral hydrate in solution may then be given by bowel. Ten or twenty grains more may be given four to six hours later, if indicated. Where chloral is contraindicated because of threatened eclampsia sodium bromide, twenty grains by bowel may be substituted for the chloral. If a further quieting effect is desired, Baughman gives ⅛ grain of morphine. None of these drugs, however, is given within an hour before the baby is born. For the acute pain usually experienced when the head is passing through the cervix a few whiffs of ether or chloroform are given. Chloroform acts more quickly and nauseates less than ether, but is to be avoided where the liver and kidneys are not in good condition. When the head is passing over the perineum Baughman always uses ether or chloroform unless there is absolute contraindication on the part of the mother, and as the baby is about to be born pushes the anesthetic from obstetric to operative anesthesia.

Prophylactic Typhoid Inoculation in Pregnant and Puerperal Women.—Engelhorn (*Berlin. klin. Woch.*, Jan. 31, 1916) reports that seventy pregnant and fifty puerperal women were immunized against typhoid without any ill effects whatever. There was no single instance in which labor was induced by the inoculations, although they were all made in the latter half of pregnancy. The blood from the umbilical vein of the fetus was taken in thirty-seven cases and tested for agglutinins, but it always proved negative, suggesting that the immunity is not transferred to the child in utero.

Real Value of Climate.—C. M. Hendricks (*Southern Medical Journal*, August, 1916) concludes from his study of climate as a therapeutic agent that it is safe to say that the climate is most favorable which presents the meteorological conditions which to a greater degree than before and more constantly permit the patient to lead the necessary outdoor life with ease, safety, and economy of vital expenditure. The accompanying change of scene and surroundings may be expected to act advantageously in an indirect way. In making any proposed change of climate attention must be given to the facilities in the new region for obtaining suitable food, accommodation, care, and medical supervision. If these conditions can be as well met in a better climate as at home the patient should be advised to make the change, but if his financial, social, or domestic circumstances are such that he cannot in a new climate secure proper medical attention, or if his mental attitude is such as to make separation from home inadvisable, he should not be sent away.

Some Notes on the Treatment of Constipation.—Henry A. Rafsky (*Medical Review of Reviews*, August, 1916) divides constipation into atonic and spastic, and maintains that not only must it be determined to which class the case belongs, but that each case must be studied and treated as a distinct clinical entity. Regarding the treatment of atonic constipation such etiological conditions as chronic disease, tumors, and uterine displacements which act through the production of local pressure are not considered. The patient should be induced to go to the toilet at the same hour each day, whether there is any bowel movement or not. A bulky diet that will leave a rather large residue in the intestinal canal is essential, so he recommends bran bread, graham bread, raw and cooked fruits, cabbage, turnips, parsnips, jam, butter, salad oil, etc. Large quantities of fluids should be drunk, at least seven or eight glasses of fluid in the twenty-four hours. In many cases there is an increased digestibility and an almost complete absorption of the cellulose, which leaves a small residue. Carbohydrates and proteins are easily digested and absorbed, fats less so, hence the latter should constitute a large part of the diet. In ascertaining a patient's tolerance for the degree of digestibility and absorption we must keep within the limits of the functions of the stomach. "In trying to cure the bowel do not bring trouble to the stomach." Exercise, massage, and electricity are of value, and so are mechanical supports in some cases. Mild, stimulating cathartics should be used only for brief periods of time. These include senna, cascara, phenolphthalein, and mineral waters. Agar is of value because it increases bulk by taking up water, and must be used in large and increasing doses to obtain results. Mineral oils cannot be used indefinitely. The treatment of spastic constipation is quite different. The aim is to quiet excessive activity, so instead of bulky food we give such as is concentrated and easily digestible, like scraped beef, rice, tapioca, and cooked green vegetables. Good results have been obtained by putting the patient to bed on a milk diet for five or six weeks. Exercise and massage are contraindicated; the value of electricity is questionable. Cathartics should not be given. More can be accomplished with a dose of atropine with morphine than with the most powerful cathartic. The intestines already are overstimulated and need rest.

Chronic Intestinal Stasis from the Viewpoint of the Internist.—Charles D. Aaron (*Buffalo Medical Journal*, August, 1916) says that many cases of chronic intestinal stasis prove after operation to have been nothing but spastic constipation. Treatment is not a matter of plumbing, but of improving the general nutrition and strengthening the muscles of the abdominal walls. Patients who are poorly nourished should be well fed, the diet should be as nutritious as possible and contain a large proportion of fats and oils which form laxative soaps. Sometimes it is necessary to resort to forced feeding. Hydrotherapeutic measures, cold water, half baths, and the Scotch douche on the abdomen, with rubbing and slapping are valuable. Systematic respiratory gymnastics several times a day. The muscles of the body may be stimulated by dry rubbing of the skin with rough towels. Massage is good to strengthen the abdominal muscles. Bandaging the abdomen acts beneficially. All of the patients need iron, which may need to be given by intramuscular medication. The sovereign remedy is atropine, or belladonna. Daily enemata of from half to one pint of olive oil also are useful. Other cases of chronic intestinal stasis are really those of atonic

constipation, which needs a different treatment. The diet should be large and bulky. The therapeutic result is to render the feces more voluminous, softer, and more liquid, so as to bring peristalsis into play. Agar is hard to digest, but absorbs and retains moisture, thus permanently increasing its own volume, resists the action of intestinal bacteria as well as that of enzymes, and gives bulk without introducing objectionable products of decomposition. It is not a purgative, but belongs to the diet in intestinal stasis just as do fruits and vegetables rich in cellulose. As it is harmless its use may be continued for months. Petroleum jelly of the best quality seems to act better than Russian mineral oil.

Swimmers' Conjunctivitis.—Harry S. Gradle (*Ophthalmology*, July, 1916) says that the best treatment he has been able to find, and he has tried everything he could think of, is a one per cent. solution of silver nitrate daily, and a ten per cent. solution of argyrol three times a day or more. The silver nitrate seemed most effective when dropped directly into the conjunctival sac, for forcible closure of the lids spreads the caustic into the depths of the transitional folds, the parts most affected, which are not reached by simply brushing the fluid on the everted lids. It must be understood that in these cases there is no involvement of the cornea, or of the deeper structures of the eye; such troubles are not likely to occur in pure cases of swimmers' conjunctivitis.

Septic Wounds.—Kenneth Goadby (*Lancet*, July 15, 1916) has worked out a comprehensive plan of treatment for infected sinuses. It should first be determined whether underlying bone is involved and whether there is sequestrum formation. In either of these cases anaerobic organisms will almost certainly be present if the wound is a military one. An autogenous vaccine, preferably sensitized, should at once be prepared from the sinus flora. If the first injection of such a vaccine produces a constitutional reaction the danger of lighting up the infection through operation is evident, and this procedure should therefore be delayed for at least three weeks or until efficient immunization has been secured. If the patient be immunized prior to operation, the anaerobic organisms may be disregarded as sources of danger, but efficient drainage should be provided. For the anaerobes to become pathogenic it seems requisite that the soil be prepared by the growth of aerobic organisms, especially those of the proteus group. Chronic sinuses which alternately heal and break down should be treated with vaccines preliminary to surgical operations.

Practical Method of Minimizing the Pain of Labor.—H. W. Kostmayer (*New Orleans Medical and Surgical Journal*, August, 1916) advocates the following method: As soon as the pain of the first stage becomes definitely annoying, chloral is given in a ten grain dose, and is repeated in forty-five to sixty minutes, as indicated, as much as three doses being given if necessary. When the character of the pain changes to the bearing down of the second stage, an eighth of a grain of morphine is given hypodermically as soon as this pain is severe enough to warrant it. It is rarely necessary to repeat the morphine, though this may be done safely after an hour or two. If labor is retarded in the least, or if in the judgment of the physician labor might safely be hastened, pituitrin is given hypodermically in graduated doses. As the presenting part begins to dilate the vaginal orifice, ether is given by the drop method at the beginning of each pain, and continued until the pain subsides.

Vesicular Eczema.—P. G. Unna (*Berlin. klin. Woch.*, January 17, 1916) states that the treatment of the infected exudative process present in these cases demands the employment of the most powerful of our drying agents, and that pastes of zinc sulphate or zinc sulphate with chalk are very useful. A new water soluble varnish, called gelanth, has been brought forward; it is composed of tragacanth with superheated gelatin. This forms a most excellent base for medicaments suitable for this form of eczema. Two useful formulas are:

℞ Ichthyolis, ...5.0;
Gelanth, ...ad 100.0.
M.

℞ Resorcini, }
Ichthyolis, } .....āā 5.0;
Acidi salicylici, ...2.0;
Gelanth, ...q. s. ad 100.0.
M.

Of these the former is the milder and the latter the more active. Both are particularly suitable where it is inconvenient to cover the part with a dressing, since they form dry coverings and remain on the surface for a relatively long time. In the second of the formulas, the gelanth may be replaced by simple ointment when it is to be used on the hairy surfaces.

Treatment of Hemorrhagic Diarrhea.—Moszkowski (*Berlin. klin. Woch.*, Jan. 31, 1916) states that in all varieties of resistant bloody diarrhea, of whatever etiology, the local application of an emulsion of iodoform in acacia will almost invariably give prompt and permanent relief, both from the hemorrhagic diarrhea and from other distressing symptoms such as tenesmus. The emulsion to be used has the following composition:

℞ Iodoform, ...80.0;
Acacia, ...100.0;
Distilled water, ...180.0.

A soft colonic tube should be slowly introduced to a distance of fifty centimeters, which can readily be accomplished with a little practice. Through this about fifty c. c. of the emulsion should be injected by means of a glycerin syringe. The majority of patients can retain this injection for two or three hours without discomfort. No preliminary intestinal lavage should be done on account of the irritation which it usually produces. This injection may be repeated daily without fear of intoxication from the iodoform, although the amount injected is about ten grams per day. In a series of cases complete cure followed from one to nine such injections. The medication acts as a sedative and protective by virtue of the acacia, and as a sedative, astringent and antiseptic through the iodoform. The latter constituent seems to promote the healing of the ulcers in a satisfactory manner.

Miscellany from Home and Foreign Journals

Brain Injuries.—B. F. Zimmerman (*American Journal of Surgery*, August, 1916) is convinced that many patients with fracture of the base recover without operative treatment. He is of the opinion that fractures of the base are not entirely hopeless as was formerly taught and he is not one who believes that if the patient gets well he did not have a fracture of the base, however much the symptoms may have indicated it. He is sure that he has seen several such patients recover. The percentage of cures will be greater if a decompression operation is done to relieve, to an extent at least, the threatened anemia of the bulbar centers.

Treatment of Unstable Cartilage of the Knee.—Royal Whitman (*Medical Record*, July 22, 1916) states that this injury is common and that manipulation is frequently necessary at the time of accident in order to replace the cartilage. In persistent instability the cartilage should be removed, because its presence is not essential and when loose it is a foreign body. The operation is done readily, no drainage is necessary, and the knee is kept in a plaster splint for two weeks, after which strapping is used for support. If there is a tendency to valgus, the soles are thickened on the inner side or arch supports are worn. Recovery is usually rapid after operation and is complete in a few weeks.

Conjugal Paresis.—H. H. Drysdale (*Jour. A. M. A.*, July 29, 1916) reports an interesting instance of this condition in which the paresis developed in the husband eighteen years after infection and in the wife about two years later. Inasmuch as the couple were married two years after the husband's infection the interesting question of the incubation period in the wife was raised, but could not be answered. Both cases progressed rapidly after their frank development. The couple had one child, apparently normal, mentally bright, and well developed. The child was eight years old when examined and then showed a positive Wassermann reaction in her blood serum. In the course of the discussion of this paper several other cases of conjugal paresis, and paresis arising in two or more members of the same family, were mentioned.

Use of the Elastometer in the Study of Edema.—A. B. Schwartz (*Archives of Internal Medicine*, March, 1916) calls attention to the superiority of Schade's elastometer in the study of edema over the palpating finger, which not only fails to give an accurate idea of fluctuations in edema, but is at times powerless to detect edema until the body weight has been increased six kgm. thereby (Widal). The measurement of edema with the elastometer is made by noting the extent of depression caused by the sinking of a weighted disk into the skin and subcutaneous tissue. Evidence of loss of tissue elasticity may, with this instrument, be found to persist in patients with nephritis or endocarditis despite the disappearance of other signs of the disease. This clearly indicates the advisability of continued observation in cases of this nature.

Bacteriological Study of Some Stillbirths.—Joseph B. De Lee (*Jour. A. M. A.*, July 29, 1916) reports five cases in which a child was born showing evidences of infection, while the mother remained quite well. In two cases the infant was born alive; in the others it had died before birth. Cultures taken from the child's secretions or blood in each case showed pathogenic organisms; in two there was the pneumococcus and in the others a streptococcus. In these cases the mother's parturient tract suffered lacerations and in one there was a post partum hemorrhage requiring tamponade, but in all the mother remained well and showed no signs of infection. In most cases there had been some mild infection, such as pharyngitis, in the mother shortly preceding labor, but in some the woman was apparently perfectly normal.

Hereditary Rachitis.—Ernst Schloss (*Berlin. klin. Woch.*, Jan. 31, 1916) finds that the soft skull found in about twenty to eighty per cent. of new born infants is merely the result of a delayed ossification which rests upon an insufficient supply of bone forming elements. The underlying cause of this deficiency in ossification cannot yet be determined, but three possible factors may be considered: That it is the natural result of the influences of domestication; that it results from temporary maternal disturbances; or that it is a direct, inherited specific disease. But in the majority of cases it is certain that this deficient ossification is not due to an inherited rachitis. However it is at the least a good foundation upon which rickets may develop and probably accounts for the very early manifestations of this disease in some cases. The condition may properly be regarded as indicating a rachitic disposition, constitution, or diathesis.

The Action of Caucasian Benzin on the Animal Organism.—U. P. Kravkoff (*Roussky Vratch*, April 9, 1916) determined the effect of benzin from various sources on white mice, rabbits, cats, and frogs. He found the action more or less the same regardless of the quality of source. In concentration of 0.0005 to 0.01 gram of benzin to one liter of air no marked effect was noticed even if the animals remained in this atmosphere from twenty-four to forty-eight hours. Doses of 0.02 to 0.03 gram caused slight poisoning. This was more marked in concentration of 0.05 to 0.06 gram, and even then the animal could remain for several hours in this atmosphere, only a few of them dying. Concentrations of 0.1 to 0.3 gram to one liter of air proved invariably lethal. The action seemed to be exerted mainly on the central nervous system, which after a brief stimulation was paralyzed. The cause of death was paralysis of the respiratory centres, the failure of respiration being preceded by marked tetanic convulsions. Locally, irritation of the mucous membranes of the eyes, nose, mouth, and respiratory passages was observed. It was also noticed that after profound poisoning, the animals recovered when brought into the fresh air.

Etiology of Surgical Scarlatina.—John B. Roberts (*Annals of Surgery,* August, 1916) says that several recent etiologic studies have been reported by investigators as holding out hope of the discovery of the organism causing scarlet fever. The latest, so far as he knows, is that of F. B. Mallory and E. M. Medlar of Boston, detailed in the *Journal of Medical Research,* March, 1916. The work was done in the Pathological Laboratory of the Boston City Hospital. This Gram-positive bacillus, which is more decidedly Gram-positive than the diphtheria bacillus, is described and thought by them to be a true bacillus scarlatinæ. The coincident streptococcus infection often complicated the investigation. Malory, years ago, thought the cause of scarlet fever to be protozoan; his interest in the subject continuing all these years seems to add force to the probable accuracy of his present investigation and the value of his opinions.

Nutrition of the Pregnant Woman and the Condition of the Child.—G. F. Darwall Smith (*Lancet,* July 8, 1916) obtained material for this study from the maternity hospitals of London and of Dublin, comprising a total of over 6,000 cases. Many percentage results of special analyses of the material are given, but the general conclusions adequately summarize the results. Primarily a state of average nutrition on the part of the mother is the most favorable of all the conditions. A state of nutrition above the average decidely increases the average weight of the full term infant and increases the proportion of mothers who are able to nurse their babies. Finally, a condition of poor nutrition of the mother at confinement greatly raises the proportion of still births and of premature births, somewhat reduces the average weight of the full term infant, and materially raises the postnatal infantile mortality, but has very little effect on the progress of the infants during the first ten days.

Surgical Lessons of the European War.—A. M. Fauntleroy (*Annals of Surgery,* August, 1916) says that it would seem that the Dakin fluid is the antiseptic of choice among the majority of those who, at one time or another, have had recourse to the antiseptic method of treatment. This antiseptic fluid, which is a 0.5 per cent. concentration of sodium hypochlorite, is made by dissolving 140 grams of dry carbonate of soda in ten litres of sterile water. To this is added 200 grams of chlorinated lime and the mixture is well shaken. After a half hour the supernatent clear fluid is siphoned off into another bottle, through a cotton plug or filter paper, and then forty grams of boric acid are added to the clear filtrate. The solution is neutral to litmus, is non-irritating and is the proper strength for wet dressings and irrigations. The solution should be made fresh every three or four days and the dry stock ingredients should be kept in covered receptacles. It is a significant fact that the Dakin fluid is preferred above all other antiseptics by the majority of medical officers who are bearing the heat and burden of the day at or near the front, while other methods receive support on theoretical grounds from those who are mostly associated with a long distance view of the war situation.

Deep Percussion in Subacute Intraabdominal Disease.—H. Neuhof (*Archives of Diagnosis,* April, 1916) alludes to the value of deep percussion in subacute or largely subsided intraperitoneal affections as residing in the fact that tenderness is elicited when deep palpation may not disclose any specially painful area. It proved useful in the examination of the obese and of those who do not relax their abdominal wall sufficiently for satisfactory palpation. Two forms of deep percussion are used, one the ordinary deep percussion employed in chest examination. A moderate amount of rebound force may be necessary to disclose the painful area. When this fails, or the result is doubtful, the second method is used, which consists in tapping the abdominal wall with a finger of the right hand. The percussion tenderness is almost always found definitely circumscribed in a small area over the diseased organ. Its degree is not necessarily proportionate to the severity of the lesion found at operation, mild, subacute, or subsiding lesions sometimes causing considerable tenderness. The latter is readily obtained when the abdomen is held rigid—an important advantage over deep palpation. In a number of instances, in Neuhof's experience, deep percussion was the only physical procedure leading to correct diagnosis, as subsequently proved at operation.

Diagnosis of Mixed Typhoid and Paratyphoid Infections.—A. Chantemesse and A. Grimberg (*Presse médicale,* June 22, 1916) describe the technic they have elaborated for the detection of intercurrent paratyphoid infection in typhoid fever or of simultaneous typhoid and paratyphoid invasion (see N. Y. Medical Journal for August 5, 1916, page 279). After describing their procedures for the cultivation of the organisms of the typhoid group on bile and for the preliminary rough differentiation of the typhoid and A and B paratyphoid organisms in a patient's blood by noting the effects produced on glucose and on lead acetate paper, the authors take up their recently elaborated technique for the quantitative estimation of these three organisms by a differential agglutination test. A titrated suspension of typhoid or paratyphoid bacilli, sterilized by heating to 56° C., is poured into a series of small conical tubes up to the one c. c. mark. Each c. c. contains one billion of dead bacilli. If now a drop or a fraction of a drop of the patient's serum is added to one of these tubes, at the end of a few hours one can recognize with the naked eye, according to the flakes that have formed, whether agglutination has taken place and what the maximum dilution is at which such agglutination is noticeable. Thus a curve of the agglutinating power of the blood in typhoid fever can readily be plotted by examinations every five days. As the disease reaches the middle of its course or the typhoid agglutination power increases, agglutination power against the A and B paratyphoid organisms appears and progressively increases, typhoid agglutination meanwhile sometimes decreasing. Proper elimination of coagglutinins and cosaturins as disturbing factors requires that the amount of serum shall bear a special relation, varying with its agglutinating power, to the amount of bacillary suspension used in making the

tests. Using one drop, or one twentieth c. c., of serum in each test, the number of billions of bacilli to be added to it is determined by multiplying by twenty the denominator of the smallest fraction of a drop of the serum which will show agglutination when added to one c. c. of bacillary suspension, and then dividing the product by 440. Thus the amount of suspension to be added to a serum of which one sixty fourth of a drop will begin to agglutinate one c. c. of the suspension is 1280 divided by 440, or about three billions of bacteria, i. e., three c. c. of the suspension. With a little practice the procedure is readily carried out by the practitioner himself, who is enabled, without a microscope, at all times to gain a much more precise knowledge of the defensive power of the body, as well as of superadded invasion of other bacilli of the typhoid group, than is afforded by blood cultures.

Deformities of the Nasal Septum. Their Correction by an Improved Technic for Submucous Resection.—J. L. Maybaum (*American Journal of Surgery*, August, 1916) summarizes as follows on the foregoing subject. 1. The type of septal deformity and the indications for performing a submucous resection should be thoroughly considered before deciding to operate. 2. Adenoids and narrowing of the nares should receive proper operative attention in order to obtain the fullest benefits from submucous resection. 3. The supine position of the patient, the head slightly elevated, is the ideal position while operating. Shock is eliminated, better access to the floor of the nose is obtained. 4. Under favorable conditions, packing of the nose may be dispensed with after the operation. 5. Postoperative manipulations in the nose should be avoided for a few days, so as to minimize the possibility of infection.

Focal Infection in Relation to Certain Dermatoses.—M. L. Ravitch (*Jour. A. M. A.*, August 5, 1916) considers that the work of Rosenow, now confirmed by others, has opened up a wide field for research and advance in dermatology, especially along the lines of etiology. Many conditions hitherto denoted "idiopathic" on account of ignorance of their etiology have now been definitely placed in the realm of secondary symptoms of focal infection and their treatment made much more satisfactory. Thus the many forms of erythematous eruptions associated with rheumatic disturbances are due to the presence of the infecting organism, which has frequently been isolated from the skin lesions themselves. Other streptococcal infections have been found to underlie many different dermatoses. Herpes zoster has been found to be due to furunculosis in several instances. Septicemia is often associated with such skin manifestations as erythemas, papular, urticarial, hemorrhagic, bullous and herpetic eruptions. Gonorrheal infection is associated with exudative erythema, keratosis and parakeratosis, and recurrent eczemas are often due to gastrointestinal diseases such as ulcers and cancer. Throat and dental infections provide perhaps the commonest sources of many of the hitherto obscure skin disorders, and the latter almost always yield to treatment or disappear spontaneously after cure of the focal infection.

A Method of Treating Cysts of the Breast.—Francis J. Shepherd (*Annals of Surgery*, August, 1916) states that a number of years ago he was asked to assist a surgeon in an operation for the removal of the breast from the wife of a colleague. The case was supposed to be malignant, without any involvement of the axillary glands; the tumor was hard, nodulated, had been noticed for some weeks and appeared to be increasing in size; it was situated in the lower zone of the right breast. The breast was removed and on examination the tumor proved to be a simple cyst containing clear fluid; it was so full of fluid that there was no sensation of fluctuation. This case impressed Shepherd much, and he then suggested to his colleague that if the cyst had been tapped it would have collapsed and there would have been no necessity of removing the breast. After this in any doubtful case he always puts a needle into the growth; if it was cystic the fluid was evacuated and the tumor instantly disappeared, and if it was a solid growth it was apparent. In some cases of scirrhus the resistance and peculiar sensation conveyed enabled him to make a diagnosis. As long as the fluid evacuated from the cyst was clear he had no doubt of its non-malignancy, but if it was bloody fluid then the case was operated upon.

Finger Prints in the Diagnosis of Traumatic Neuritis.—R. Cestan, P. Descomps, and J. Euzière (*Presse médicale*, June 8, 1916) have found that in injuries of the median and ulnar nerves, deviations from the normal finger print, compared with the uninjured side, take place in all but three per cent. of instances. In injuries of the radial nerve they occur in about one half the cases, but are less marked than in the median and ulnar cases. In irritative contractures they are almost constant, but in functional paralysis never occur unless some related organic injury—e. g., an abrasion of the humerus—exists. In making the prints the finger tips are first cleansed carefully with oil of turpentine on a cotton pledget, next thoroughly dried, then at once inked with a roller previously covered evenly with printer's ink. The prints are next made by contact with stiff paper tacked to a board, the application of the finger tips being carried out by the examiner himself, to secure evenness of pressure and exactly comparable prints. Photographic enlargements may be made by making the original prints on clean glass plates and using them as negatives in the enlargement. The pathological changes met with include white streaks across the prints, due to tissue emaciation; abnormal plainness of the pores and loss of definition of the epidermal ridges, due to secretory and vasomotor disturbances; fragmentation or localized complete obliteration of the ridges. The last is an indication of true trophic disturbance, observed almost exclusively in injuries of the median or ulnar nerve. Apparently there is no definite relationship of the finger print changes to the extent or exact location of the nerve disorder. Systematic finger study is, however, of unquestionable value as a new clinical, diagnostic method in peripheral neuritis. In cases with the most pronounced finger print changes, identification of the individual by means of the prints may be difficult. For this purpose prints from the sound side alone should be taken into account.

Common Sense and Consumption.—John B. Hawes, Jr. (*Boston Medical and Surgical Journal*, July 27, 1916) gives the following rules in making a diagnosis of tuberculosis: Do not make up your mind beforehand that the case is or is not one of tuberculosis. Do not hurry. In cases where the sputum is lacking or negative, two or three examinations of the patient and many examinations of the sputum are often necessary. In some not uncommon cases a positive diagnosis may be made from the history, and constitutional signs and symptoms alone, without signs in the lungs; less often we can safely make a diagnosis on lung signs alone without marked constitutional disturbances. In the vast majority of cases there should be present both signs in the lungs, generally including rales at one time or another, and constitutional signs such as fever, rapid pulse, subnormal temperature, loss of weight and strength. Processes at the apex are considered tuberculous until proved the contrary; processes at the bases are thought nontuberculous until the contrary is proved. A hemorrhage, not including minute streaks or flecks of blood in the sputum, means tuberculosis until the contrary is proved. The x ray gives confirmatory evidence which rarely is of great value in diagnosis when taken by itself. Tuberculin tests are of little value in adults and may do harm. Observations of temperature and pulse, taken at home three or four times daily for three or four days, give evidence of the greatest value. The most important evidence is that obtained from a careful and detailed study of the patient, his family history, habits, surroundings, and occupation. To sum up, the diagnosis of early pulmonary tuberculosis or clinical consumption requires patience, perseverance, boldness, and, above all, common sense. The physician must remember that he is dealing with a human being, and not merely a set of lungs, normal or abnormal.

Differential Diagnosis of Bullous and Vesicular Eruptions in Children.—M. Scholtz (*Lancet-Clinic*, July 15, 1916) lays stress, as a differential feature of eczema, on the marked tendency of the lesions to coalesce, forming irregular patches spreading by continuity. A diffuse, irregular inflammatory base occupying the whole area of individual vesicles is also an important differential point. The vesicles of eczema rupture easily, sometimes spontaneously. Impetigo contagiosa, often unrecognized and treated as eczema, starts as vesicles or bullæ, much larger than eczematous vesicles, flat and even umbilicated, with a narrow surrounding zone of hyperemia. The vesicles become purulent, rupture, and covered with characteristic soft, bulky crusts. Scabies, because of scratching and secondary infection, may be completely disguised by secondary vesicular and pustular eczema. Burrows may be particularly hard to discover in these cases, and the diagnosis should rest chiefly on the situation of the lesion, viz., the webs of the fingers, flexor surfaces of the wrists and arms, mammæ or penis, anterior surface of the chest, abdomen, and inside the thighs. Atypical and strongly developed miliaria (prickly heat) may lead the physician astray. It should be remembered especially that the minute miliaria vesicles, though closely crowded, are always discrete, and though tensely filled, seldom rupture spontaneously, but disappear by absorption and desiccation. Herpes simplex is, as a rule, properly recognized from its sudden appearance at mucocutaneous junctures, cluster like grouping, superficial character, rapid involution, absence of itching, and association with fever or dyspeptic symptoms. Herpes zoster can usually be differentiated by the prodromal neuralgic pains, sudden appearance in crops, supraorbital, cervical, or pectoral, unilateral situation, and closely set clusters of vesicles on acutely inflamed and sharply defined bases. Dermatitis herpetiformis, though often mistaken for eczema or scabies, can readily be differentiated from the former by the herpetic grouping of the vesicles, the discrete character of the lesions and their lack of a tendency to coalesce, by their breaking out intermittently on widely scattered parts of the body, and by the absence of inflammatory reaction, of spontaneous rupture of the vesicles, and of weeping. From scabies the affection is differentiated by the distribution as well as the character of the lesions. Among the bullous eruptions of children, bullous syphilide, pemphigus, bullous impetigo, bullous erythema multiforme, and drug eruptions are especially to be borne in mind.

Contusion of the Hip.—Raymond Grégoire (*Paris médical*, June 17, 1916) calls attention to the fact that whereas in injuries to the shoulder, elbow, wrist, and knee a diagnosis of contusion is rarely made, these joints being so superficial that a sprain, fracture, or hemarthrosis is detected with relative ease, contusion of the hip is still a diagnosis frequently rendered, direct examination of the injured structures being practically impossible. In fact, a definite group of signs has been held to be characteristic of hip contusion, viz., pain in the region of Scarpa's triangle upon motion; apparent shortening of the injured limb, which disappears upon placing the anterior superior iliac spines of the recumbent patient in the same horizontal line, and an incomplete loss of motor function, the limb tending toward external rotation, but being voluntarily maintainable in inward rotation when placed in this position. Rapid disappearance of the pain, motor incapacity, and external rotation has, moreover, been considered indicative of contusion of the hip as against fracture of the femoral neck. Grégoire points out, however, that in true hip contusion, pain and disability may persist for a long period, then suddenly disappear. On the other hand, in many cases apparent contusion of the hip suddenly becomes transformed into a manifest fracture of the neck. The author reports three cases of so called hip contusion which were actually impacted intracapsular fractures and would have remained improperly diagnosed without x ray examination. The complete functional disability held to be a characteristic of fracture is, as a matter of fact, not a constant sign. Kirmisson, Chaput, and others having called attention repeatedly to undoubted fractures of the neck in which motion and even walking were possible for a period after the injury. On the whole, Grégoire is led solemnly to warn against diagnosticating contusion of the hip without having recourse to a carefully conducted x ray examination.

Proceedings of National and Local Societies

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-first Annual Meeting, Held at Washington, D. C., May 9, 10, and 11, 1916.

The President, Dr. J. Wesley Bovee, of Washington, D. C., in the Chair.

(*Continued from page 332.*)

Experimental Syphilis.—Dr. F. W. Baeslack, of Detroit, stated that the causal relationship of Treponema pallidum to lues was established, 1, by the observation of the occurrence of the organisms in the syphilitic lesions incident to the various stages of the disease; also the distribution of Spirochæta pallida in the lesions of acquired and congenital syphilis. 2. The successful inoculation of lower animals from human lesions, thereby producing syphilis experimentally in rabbits, monkeys, and other animals; the methods employed and discussion of the character of the lesions, and the observation of generalized syphilis in experimentally inoculated animals. 3. The growing of Treponema pallidum in culture media free from contamination, the transfer of these cultures through many generations, and the successful inoculation of lower animals with the cultivated organisms; the loss of virulence of the organisms against the lower animals after extended cultivation; and the cultural characteristics and morphology of Spirochæta pallida. 4. Immunological studies, pseudoprimary lesions, and true reinfection, as well as superinfection, as expressed in the lesions in the various stages of syphilis, which did not harmonize with their conception of immunity.

The author spoke of attempts at immunization by means of spirochetal vaccines, and described the occurrence of agglutinins in the serum of animals treated with suspensions of dead spirochetes. He spoke of the absence of immunity as demonstrated by the ability to reinoculate animals which had recovered spontaneously or subsequent to treatment. He pointed out that an altered reactivity of the body was the possible explanation for the occurrence of the lesions peculiar to the various stages of syphilis.

Syphilitic Fever.—Dr. Frederick J. Taussig, of St. Louis, read a paper on this subject in which he summarized as follows: 1. The diagnosis of syphilitic fever could rarely be made with absolute certainty, but they should more often consider it as a possibility and institute antiluetic measures in suitable cases. 2. Secondary syphilitic fever occurred in a mild form in twenty per cent. of patients at the outbreak of the rash, and at times was prolonged and more severe in its course. 3. Late secondary syphilitic fever was occasionally seen in a pronounced form after confinement or in gynecological patients. 4. Tertiary syphilitic fever was practically never due to syphilitic lesions in the female genital tract. It might, however, complicate a gynecological or obstetrical condition, and, owing to the difficulty in locating the site of the tertiary lesion, lead to a wrong diagnosis as to the cause of the fever. All doubtful cases should be subjected to a Wassermann test and, if positive, receive antiluetic treatment. 5. Syphilitic fever was probably due to the reaction of the body to the toxins produced by the spirochete which, under certain circumstances, or in certain individuals, gained an entrance to the circulation.

Clinical Course of Cancer in the Light of Cancer Research.—Dr. Harvey R. Gaylord, director of the State Institute for the Study of Malignant Disease, Buffalo, announced that cancer was not one disease, but a great group of diseases. The various types of sarcoma in chickens caused by filterable viruses had taught them that there were neoplasms with specific agents which determined the character of the tumor. Progress required that cancer of different organs be treated as individual diseases and studied individually. The study of immunity to inoculated cancer threw new light upon the clinical course of the disease. Successful surgery, x ray, and radium treatments all depended upon immunity. Early operation owed its success to the fact that immune reactions in spontaneous cancer were strongest in the early stages of the disease. The effect of chloroform and ether anesthesia and loss of blood from surgical operation was shown to exercise a destructive effect upon immunity.

Cancer of the Uterus and Its Treatment.—Dr. John G. Clark, of Philadelphia, classified cancer under three divisions as regards its treatment: 1, the radically operative; 2, the radical use of the cold cautery, and, 3, the use of radium or mesothorium. Statistics as to surgical results were now upon an accurate basis and demonstrated a higher percentage of cures from the radical abdominal operation than had been achieved by the less radical vaginal and abdominal methods. In rebuttal there might be offered the much higher primary mortality and the greater number of disabling sequelæ from the former over the latter operation. The dangers of the radical operation were great, even in the hands of the expert, and prohibitive when performed by the surgeon of limited experience. Many so called radical operations were mere makeshifts, the patient being subjected to much greater hazards without appreciable gain over simpler methods, by an attempt to execute an operation which fell lamentably short of an ideal standard. As yet the cold cautery was in the proving ground and in rather a procedure which, to be successful, must be radical, and, therefore, was likely to be attended with a high primary mortality as well as serious sequelæ. It must, therefore, show a higher percentage of ultimate cures to make it a worthy competitor of the radical operation.

In the speaker's experience of two years with radium, it had given encouraging promise, first, as a palliative remedy, and, secondly, as a tentatively curative one. It was in no sense a miraculous panacea, for a considerable number of cases were not helped, for the malignant process did not appear to be halted, but might actually be expedited. The sequelæ, however, following its judicious employment were comparatively insignificant compared with the foregoing methods, and, therefore, if the patient was not helped she was, at least, spared the

added miseries of unfortunate accidents. Because the radium was not a trustworthy agent in all cases, and because as yet the type of cancer which would be helped could not be forecast, surgical measures must still be invoked, but might be supplemented by radiation.

The dictum of the last few years, "In case of doubt, extirpate the uterus," was now modified, for in all such instances they now applied radium. Thus far in no instance had hysterectomy been performed when radium had acted beneficially, for it did not appear logical that an operation could accomplish anything further. As experience now pointed, it would appear that radioactive agents were to serve as excellent supplementary remedies to surgery, offering better results in the operative cases and a definite hope in the inoperable.

The Extended Operation for Carcinoma of the Uterus.—Dr. Reuben Peterson, of Ann Arbor, presented the following summary and conclusions: 1. Further experience with the radical abdominal operation for cancer of the uterus confirmed the belief that it was an exceedingly dangerous procedure and would always be attended by a high primary mortality. 2. Even if the percentage of operability of cases of cancer of the uterus markedly increased in this country and elsewhere, there would always be borderline cases attended by a high primary mortality. 3. This was true because it was not always possible, even with the greatest care in examination of the patient prior to operation, to estimate the extent of the disease. 4. Errors in judgment meant death from shock if the disease was too far advanced or if there had been failure to complete the radical removal of the cancerous uterus. 5. In spite of a high primary mortality, however, it was the only procedure, with the possible exception of the extended vaginal operation, which held out any reasonable promise of a permanent cure. 6. Primary and end results of the radical operation for cancer of the uterus must be considered together, in order to judge of the good accomplished in a given series of cases. 7. Unless the operations were radical, the end results would be poor, and if they were radical the primary mortality must be high. 8. If the end results were poor, the burden of proof was upon the radical abdominal operator to show why he did not choose a much safer palliative procedure. 9. Since 1912, experience with fourteen ordinary panhysterectomies for cancer of the fundus showed worse primary and end results than in eleven cases previously reported where radical removal was performed. 10. This showing and the results following removal of fundus carcinoma by various methods in the Wertheim clinic, as reported by Weibel, led to the conclusion that, because carcinoma of the fundus was more easily cured than when the cervix was involved, they were not justified in thinking it could be treated any less radically than carcinoma of the cervix. 11. The primary mortality in fifty-nine cases of cancer of the cervix and fundus treated by the radical abdominal operation was 25.4 per cent. 12. The extent of the involvement in cancer of the uterus could only be determined definitely after the abdomen had been opened. If the parametria were not too much involved and the condition of the patient's kidneys, heart and bloodvessels warranted a prolonged and depressing operation, it was justifiable to attempt the radical operation. 13. During the past four years 124 cases of cancer of the uterus had been seen in the university and private clinics. The disease was so far advanced in thirty-six cases that either operation was refused or nothing was done. The cautery method was tried in fifty-eight cases and proved valueless, except as a palliative procedure. 14. In spite of attempts to educate the public regarding cancer, the cases of cancer of the uterus seen during the past four years were more advanced than had formerly been the case. 15. The end results in fifty-one patients operated upon, five or more years ago, were most gratifying. Combining fundus and cervix cases, twenty-seven of the fifty-one patients were alive and well after five years, or 56.2 per cent. of all cases operated in, while 69.2 per cent. of all those surviving the operations were alive after five years. 16. Of forty cases of cancer of the cervix operated in five years or more ago, eighteen of those surviving were alive and well. Thus 47.3 per cent. of the total number remained cured after five years, while sixty-two per cent. of those surviving remained cured. 17. These percentages were obtained by Wertheim's formula where patients dying of intercurrent disease, or those lost track of, were subtracted from the total number of operative cases or from the number surviving. 18. The length of time elapsed since the operations upon the eighteen patients who were alive and well varied from five up to thirteen years. There was every reason to think these patients were permanently cured, although one patient did have a recurrence and died between five and six years after the radical operation. 19. In spite of the high primary mortality, the end results in those surviving the operation encouraged them to continue the procedure in suitable cases.

Heat as a Method of Treatment in Inoperable Uterine Carcinoma.—Dr. James F. Percy, of Galesburg, Illinois, said there were three stages to be recognized in the development of the cautery in the treatment of carcinoma of the uterus: First, where it was used merely to stop hemorrhage and limit offensive discharge; second, in the galvanocautery excision of the cervix uteri developed by the late Dr. John Byrne, of Brooklyn-New York. In this technic a high degree of heat was used, sufficient to cut the tissues; third, in the dissemination of a coagulating degree of heat through the widest possible area of the cancer mass, with no attempt at immediate excision of the parts. The technic of Byrne was not designed for the advanced inoperable cancer patient, the one in which the uterocervical junction was fixed, with extensive malignant and inflammatory infiltration of both broad ligaments and the parametrium. As classified today, Byrne operated only in the first stage of cervical cancer involvement. The speaker stated that his technic brought the practitioner back to the days before Byrne, to the treatment of the otherwise hopeless case, and in addition he stated that his technic opened up new possibilities in the way of further improved results, in the type of case in which Byrne secured his best results.

The author emphasized the point that the stage of operability with his present technic was easily ninety per cent., and he confidently expected that the stage of operability would be without limit in strictly pelvic cancer. He would not have the practitioner believe, however, that the ideal was mere operability. Back of it all was the hope and promise of results never before obtained by any method so far developed in that disease which had always stood as a synonym for incurableness—pelvic cancer.

In conclusion, he reemphasized: 1. The Percy technic, so called, was not a cautery operation. He removed nothing. The tissues following the application of the moderately low degrees of heat were literally coagulated and slowly dissolved. It usually took two weeks for a healthy granulating surface to appear beneath the gradually dissolving mass of inert cancer débris. 2. The operation of Byrne was a high galvanocautery incision of the cervix. There could be but little penetration of heat. Byrne recognized this when he advised that the surface left after the removal of the gross mass be seared over with the cautery knife, in order to get all the heat penetration possible. But Byrne never thought of applying heat to the degree of obtaining penetration sufficient to render movable the fixed tissues in the pelvic basin. If the fixed tissues, malignant and inflammatory, were not made freely movable, as they were normally, the heat penetration had not been sufficient, and, therefore, was ineffective. 3. To coagulate a large mass of uterine cancer required from thirty to sixty minutes; and if the broad ligaments still remained stiff or fixed, an additional ten minutes. 4. In the author's effort to emphasize the importance of avoiding the burning temperatures, he feared that he had led many surgeons to the opposite extreme, and that they were trying to destroy the activity of an inoperable mass of cancer with a temperature so low that days, rather than hours, would be required to make the heat effective. Byrne *fried* the tissues, whereas the author *broiled* or *pasteurized* them. The Byrne technic was based on the use of heat as an acute process; while the author's was not acute, but chronic, both as to time and degree. Heat, more heat, and yet more heat; but heat, not fire; broiling not frying; not roasting, but curdling; pasteurization, not desiccation; coagulation, not carbonization.

In its practical application the whole technic could be summed up in the one statement: Do not carbonize the tissues, for in the degree that this was done, in that degree was heat penetration inhibited; and heat penetration was the vitally essential thing.

High Heat Versus Low Heat in the Treatment of Cancer of the Uterus.—Dr. Herman J. Boldt, of New York, said that he had expressed himself fully on the relative value of high degrees of heat compared with low degrees of heat as a palliative therapeutic agent in the advanced stages of cancer of the uterus in an article published in the *American Journal of Obstetrics and Diseases of Women* for January, 1916, issue, and judging from the communications he had received from physicians who had had experience with the treatment, his position was amply justified. It was also corroborated by another autopsy, in addition to the one he had, by Dr. F. W. Bancroft, of New York. He did not wish to detract from the usefulness of low heat, but it should be reserved principally for a second application, after rapid destruction had been accomplished with high heat, and the charred eschar that was caused by the high heat had been thrown off; and for cases in which the cancer had so far advanced that the proper application of high heat would endanger the bladder or rectum. The danger from secondary hemorrhage was not less with low heat than with high heat. No evidence had been presented that showed the superiority of one method over the other. Heat, properly used, and applied in selected cases, sometimes gave remarkably good palliative effects; but it had been conclusively shown that cancer cells were not destroyed any appreciable distance from the surface of application, certainly not deeper with low heat than with high heat. This was proved by the examination of tissues procured at the autopsies mentioned.

Dr. Charles Mayo, when discussing the paper published in the *American Journal of Obstetrics and Diseases of Women*, asserted that the proof of the deep destruction of low heat was shown in cases that had been operated in in the Mayo clinic, lay in the fact that at the time of cauterization the disease had advanced too far for the patients to be operated upon radically, but later the uterus became mobile and was extirpated, and when these uteri were examined by the pathologist he failed to find malignant disease. This hypothesis was not acceptable to the speaker as valid proof, since the mobility might have become impeded by an inflammatory process which, as the result of the heat treatment, became dried out, as it were, and mobility of the uterus resulted; a result seen also when high heat was used. The inflammatory infiltration might subside, but the carcinomatous infiltration remained. To disprove this it was necessary for the operator, when the abdomen had been opened, to remove a part of the infiltrated area under suspicion in the pelvis a reasonable distance away from the cervix, and have it examined by a competent pathologist. If that showed cancer nests and the uterus became mobile subsequently, so that a radical operation might be done, and the specimen then removed by a radical operation failed to show cancer elements in the parametria, they were in a position to grant the deep destruction of cancer elements by the heat applied, but not until such proof had been shown.

A Study of the Pathology in Its Relation to the Etiology with the End Results of Treatment of Sterility.—Dr. John Osborn Polak, of Brooklyn-New York, gave a personal review of 798 case histories of patients from his private practice, and analyzed the many etiological factors which had entered into sterility. He discussed the individual case based upon an etiological diagnosis, and finally summarized his end results: 1. A very large number of patients with sterility applying for relief had no chance whatever of becoming pregnant, as the pathological condition was such as to make conception impossible. 2. The male was largely responsible for the poor results in treatment. 3. There was a definite chemicopathological factor in conception, at present unexplainable, which was a cause of prevent-

ing conception. 4. Operative procedures on the uterus, except amputation of the hypertrophied portion, had but a slight influence in the end results in the treatment of sterility; 5, each case must be individualized and both contracting parties carefully studied before treatment was begun.

Rupture of the Scar Following Cæsarean Section.—Dr. Palmer Findley, of Omaha, gave a survey of the literature on this subject, with a digest of case reports, for the purpose of determining whether or not one Cæsarean section called for another in the event of a subsequent pregnancy, and then drew the following conclusions: 1. A perfectly healed Cæsarean wound might be relied upon to resist the forces of labor, but in view of the fact that the integrity of the wound was an unknown factor in all cases, he was constrained to exercise the utmost caution in the conduct of every case of pregnancy and labor following Cæsarean section. 2. Failure to secure perfect healing was accounted for by departure from the principles of suture proposed by Sanger and by septic infection of the uterine wound. If they were to obtain the uniformly good results in respect to wound healing that were secured in the decade following the introduction of the Sanger method of suture, they must not deviate from these principles. 3. The possible existence of latent gonorrheal infection might defeat the most painstaking efforts to secure perfect wound healing; hence it followed that the healing of a Cæsarean wound was always an uncertain factor. 4. When Cæsarean section had been followed by a fever course, the uterine wound should be regarded as insecure in the event of a subsequent pregnancy, and should call for a repeated Cæsarean section at the onset of labor. 5. Sterilization and hysterectomy should replace conservative Cæsarean section when infection was known to exist. The alternative invited faulty wound healing, if not more disastrous results. 6. Transverse fundal, extraperitoneal, and cervical incisions had not lessened the liability of rupture in subsequent labors, but, on the contrary, had probably increased the hazard. 7. The possibility of rupture of the scar following Cæsarean section did not justify sterilization, but rather called for the exercise of masterly control in the event of a subsequent pregnancy. All such cases should be hospital cases and labor should be anticipated by timely repetition of Cæsarean section at the onset of labor if the uterine wound was known to be defective, or if some cause existed for obstruction to the delivery of the child through the natural passage. Version, high forceps, uterine tampons, hydrostatic bags, and pituitrin should never be employed in the presence of a Cæsarean scar. 8. They might conclude that in view of the evidence, that not more than two per cent. of ruptures occurred in subsequent labors, they were not justified in voicing the slogan, "once Cæsarean section, always Cæsarean section"; neither were they to rely solely upon the integrity of the uterine scar in any case. Furthermore, he concluded that the liability of rupture was a real danger and should stand as an argument against the increasing tendency to widen the scope of elective Cæsarean operations.

A Résumé of Results in the Radium Treatment of 347 Cancers of the Uterus and Vagina.—Dr. Howard A. Kelly and Dr. Curtis F. Burnam, of Baltimore, after seven years' experience, and with full knowledge of similar work in other parts of the world, could now say without hesitation that radium in sufficient quantities greatly enhanced the chance of permanent recovery of patients with uterine and vaginal cancers. In early and good operable cases, radium combined with operation added greatly to the prospect of recovery without recurrence. The most remarkable fact about the radium treatment of uterine and vaginal cancers was that it often cleared up cases which had extended too far locally and had become firmly fixed to the pelvic wall; in other words, in a class of cases which were utterly inoperable. They had had 327 patients, including borderline cases, cancers fixed to the pelvic wall, great massive cancers choking the pelvis, and many with general metastases, where the radium was used only to afford relief; yet over twenty per cent. of this remarkable group had been apparently cured. They did not pause to dwell upon the great alleviation afforded a large number of those who were not cured, but where discharges stopped, pain ceased, and health was built up. Their conclusion then was that radium had come to stay and was a most efficient agent in treating cancers of the uterus and vagina.

X Ray Treatment of Uterine Hemorrhage.—Dr. Robert T. Frank, of New York, said that x ray treatment was indispensable in gynecology, but under strict indications and limitations. The rays worked mainly by destroying ripening ovarian follicles, primordial follicles showing great resistance. When no ripe follicles were present, menstruation ceased. In fibroids there might also be a direct effect on the tumor. Fractional exposure implied frequently repeated treatments of small amount. This took more time, but permitted of finely graded doses. Intensive treatment by use of small multiple fields permitted of rapid attainment of amenorrhea. The rays could be used in all functional hemorrhages —menorrhagia or metrorrhagia—in which expert examination revealed normal pelvic organs, and in which the curettings were free of malignant changes. This saved the uterus of adolescents and women in their sexual ripeness because the bleeding could be "toned down." It also saved women in the preclimacteric age from operation, if they were bad operative risks. The speaker had used x ray in about five per cent. of fibroids. Only forty-five per cent. of fibroids required treatment. Bleeding was most readily checked by raying. In order to permit of the safe employment of x ray, the speaker postulated that no case should be rayed in which a suspicion of carcinoma or sarcoma was entertained, that no complications, such as ovarian or annexal tumors, were present, that no urgent symptoms were present. This limited the treatment to clear cases of uncomplicated fibromyoma. Preference should be given to the rays when extreme psychical unrest or severe cardiac, renal, or pulmonary disease contraindicated operative measures. The expense entailed by raying precluded its use except in well to do patients or in endowed institutions.

(To be concluded.)

Letters to the Editors

EVERYBODY'S BUSINESS IS NOBODY'S.

NEW YORK, *August 3, 1916.*

To the Editors:

Experience No. 1.—My wife and five and a half year old daughter, who had been on the south shore of Long Island for a long time before the present epidemic of poliomyelitis started, left there for Westchester County on Monday, July 17th. In order to avoid passing through New York, they motored across Long Island and ferried from Sea Cliff to New Rochelle. The police officer of that place refused to allow them to land and refused to examine the two doctors' certificates with which they were supplied, but he kindly informed them that if they came in a private launch, all would be well, as his instructions were only not to allow children under sixteen years of age to land from the ferry.

Experience No. 2.—On Monday, July 31st, my wife and child came to New York en route for New Hampshire. I obtained the certificate needed from a physician and from the Board of Health and then took the child to the Federal officer at the Grand Central Depot, who gave me another certificate. Every one was most kind and considerate and worked with dispatch; but imagine my surprise when we boarded the train and were not even asked for a single certificate.

I do not care to comment. A. M. H., M. D.

AUTOSERUM IN THE TREATMENT OF ANTERIOR POLIOMYELITIS.

NEW YORK, *August 13, 1916.*

To the Editors:

Inasmuch as serum of healthy adults is being experimentally used in the present epidemic of anterior poliomyelitis, I venture to suggest the use of autoserum instead. The dose of the autoserum may range from twenty to forty c. c., administered intravenously. Autoserum has proved to be of value in septic endocarditis, chorea, pneumonia, and typhoid fever. It may prove of value in infantile paralysis. In the employment of autoserum, the patient need be neither a lender nor a borrower.

ROBERT ABRAHAMS, M. D.

257 West Eighty-eighth Street.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The Treatment of Infantile Paralysis. By ROBERT W. LOVETT, M. D., Boston, John B. and Buckminster Brown Professor of Orthopedic Surgery, Harvard Medical School; Surgeon to the Children's Hospital, Boston, etc. With 113 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1916. Pp. ix-163.

This little volume is both timely and valuable. The author, who has had considerable experience in the treatment of infantile paralysis, has managed to compress within the compass of 160 pages all that the practitioner needs on this subject. In the first chapter there is a concise statement of what is known of the pathology, symptoms, diagnosis, mortality, and prognosis of the disease. The remainder of the book is concerned with the treatment, and this is considered at some length. During the acute phase of the disease, the main object of the treatment is to limit the destructive process; during the convalescent phase, the restoration of muscular power and the prevention of deformity are the main desiderata; in the chronic phase, the treatment is chiefly operative. The author only includes in the book what has been proved to be of value, and he ignores mere theories. Thus drug and serum treatment occupy only one page, and are summarized in the author's statement that "we have no knowledge at present of any drug or serum or means of treatment which will protect from infection, abort the attack, or prevent the paralysis." Rest, ambulatory treatment, braces, balance, prevention of deformity, restoration of nerve and muscle power, massage, heat, electricity, and muscle training are all discussed in the light of the author's own experience. Operative treatment is described in some detail, and occupies the greater part of the book. There is a short, but important, chapter on muscle training, and another on the spring balance muscle test. The book is in every way admirable, and is a splendid example of what an able author can accomplish in a small space; it will probably be welcomed by every physician living in or near the scene of the present epidemic; and it stands in pleasing contrast to the hysterical and irresponsible utterances of many would-be guides.

Sex Problems of Man in Health and Disease. A Popular Study in Sex Knowledge. By MOSES SCHOLTZ, M. D., Chief of Clinic and Clinical Instructor in Dermatology and Syphology, Medical Department of the University of Cincinnati, etc. Cincinnati: Stewart & Kidd Company, 1916. Pp. 168. (Price, $1.)

While the wages of sin is death, the lot of the prostitute, in this country at least, does not seem to develop logically from her transgression; she becomes the prey of grafting politicians, of the lower sort of police officer, of pimps and similar ornaments of society, which gives some idea of the amount of her earnings. Apart from this error of attributing directly to her "sin," the unhappy condition of the professional prostitute, Doctor Scholtz's little book is an excellent one. It is almost incredible, and makes us shudder to contemplate the vast ignorance of the simplest facts of sexual physiology that pervades the laity and renders necessary such books as this. Gonorrhea is still a joke among young men, a sort of assumption of the *toga virilis*, in spite of what we now know of the countless laparotomies among young brides directly due to the terrible disease. Gonorrhea seems to be more largely responsible for childlessness than contraceptive methods, against which there is such an outcry. We think this book is a trifle old fashioned in its view of masturbation, which is notoriously common among the lower animals in the absence of a mate. The damage done to a young man must be largely psychic and due to pernicious and lying quack literature; abstinence will quickly cure the average case of neurasthenia supposedly due to the habit. There is a much wanted warning against the clandestine prostitute, who seeks adventure for pocket money, good dinners, or the theatre. The description of, and indicated treatment for venereal disease are very well done by Doctor Scholtz, and the whole style and viewpoint of the book are excellent. Perhaps it might be better in the smaller towns for the physician or druggist to handle a book of this kind rather than the regular bookseller, of whom many sufferers might feel some diffidence in asking for it.

A Manual of Practical Laboratory Diagnosis. By LEWIS WEBB HILL, M. D., Graduate Assistant, Children's Hospital, Boston. With 11 Figures and 8 Plates—4 in Colors. Boston: W. M. Leonard, 1916. Pp. vii-179.

The author and publisher of this little volume are to be congratulated on having broken away from the modern fashion of trying to compress within a single volume all the tests which have, ever been employed. In this little book will be found a few tests, well chosen, and all of them practical for the average medical man. Tests and methods which are not of ordinary clinical application, or which can be performed only in a well appointed laboratory by an expert worker, are omitted. There must be many physicians who have been waiting for just such a book as this.

Examination of the Urine and Other Clinical Side Room Methods. By ANDREW FERGUS HEWAT, M. B., Ch. B., M. R. C. P., Ed., Tutor in Clinical Medicine, University of Edinburgh; Lecturer Edinburgh Post-Graduate Vacation Course. Fifth Edition. New York: Paul B. Hoeber. Pp. 212. (Price, $1.)

Of about vest pocket size, this manual contains the essentials of uranalysis, also of examination of the blood, sputum, pus, gastric contents, and feces. Space is saved by not dwelling upon the significance of the findings, which can be looked up elsewhere. The student can save an immense amount of time and labor by providing himself with this book, which we commend cordially.

Interclinical Notes

Dr. William Brady, in the August *Nurse*, insists that the latest fashionable disease is sinusitis—one of our most ghastly hybrid neologisms, likely to make poor Achilles Rose turn in his grave. Dr. John B. Huber boldly attacks the venereal diseases; he uses the uncommon form, *innocentium*, in the well known phrase, *syphilis insontium*. Dr. Anne E. Perkins contributes a useful paper on dangerous popular fallacies, such as salves for wounds, the milk of one cow, mother's marks, red flannel, electric belts, uric acid in the system, etc. Dr. Frederick C. Warnshuis avails himself of our curious use of some words in writing on "female catheterization." There are several valuable articles by trained nurses and a really good short story, What the Filipino Started, by Jane K. Polk. The illustrations, as usual, are attractive and well done.

* * *

A picture in *Leslie's* for August 3d shows German prisoners having their wounds bound up by their British captors. We suppose that a prisoner under such circumstances permits himself to draw a long breath of relief, even if he is careful to let no one see him in the act. To us, such a dénouement will always seem a *reductio ad absurdum* of a bloody campaign; the effect is inevitably one of anticlimax.

* * *

The *Survey* for July 22d bears on the cover a picture of the bas relief recently presented to the Women's Medical College of Pennsylvania by Dr. Rosalie Slaughter Morton, of New York. A woman sculptor is responsible for the elaborate work, Clara Hill, pupil of Augustus St. Gaudens. The central figure is a woman physician, garbed in academic gown and mortarboard.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 9, 1916:

Bean, W. S., Jr., Assistant Surgeon. Designated as a member of coast guard retiring board at Boston, Mass., vice Passed Assistant Surgeon R. A. Kearny, relieved.

Billings, W. D., Surgeon. Granted twenty-two days' leave of absence from August 22, 1916.

Blount, B. B., Acting Assistant Surgeon. Granted two days' leave of absence from August 6, 1916.

Grimm, R. M., Passed Assistant Surgeon. Directed to proceed to Columbia, S. C., Milledgeville, Ga., and Jackson, Miss., for observation as to incidence or recurrence of pellagra.

Grubbs, S. B., Surgeon. Granted five days' leave of absence from July 30, 1916, under paragraph 193, Service Regulations.

Hurley, J. R., Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

Jones, W. M., Assistant Surgeon. Granted one month's leave of absence from August 20, 1916.

Kempf, G. A., Assistant Surgeon. Directed to proceed to New York for duty in the investigation and suppression of poliomyelitis.

Laughlin, J. B., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

McKay, S. R., Field Investigator. Directed to proceed to Tuscaloosa, Ala., for duty in studies of rural sanitation in Tuscaloosa County.

Marshall, Edward R., Passed Assistant Surgeon. Granted fourteen days' leave of absence from August 10, 1916.

Mathewson, H. S., Surgeon. Directed to take charge of the Marine Hospital, Portland, Me., during the absence of Senior Surgeon P. C. Kalloch.

Miller, K. E., Assistant Surgeon. Directed to proceed to Toledo, Ill., to assume charge of studies of rural sanitation in Cumberland County.

Mitzmain, M. B., Technical Assistant. Directed to proceed to New York for duty in the investigation and suppression of poliomyelitis.

Scott, J. T., Acting Assistant Surgeon. Granted two days' leave of absence, June 1 and 2, 1916.

Slaughter, W. H., Assistant Surgeon. Directed to proceed to Calhoun, Gordon County, to investigate possible infection of public water supply.

Stimson, A. M., Surgeon. Bureau letter dated July 3, 1916, granting one month's leave of absence from July 6, 1916, amended to grant twenty-six days' leave from July 6th.

Weldon, L. O., Assistant Surgeon. Bureau letter dated July 25, 1916, granting three weeks' leave of absence from August 1st, revoked.

Wheeler, G. A., Assistant Surgeon. Directed to proceed to cotton mills villages in counties of Greenville, Laurens, and Union, S. C., to make epidemiologic studies of pellagra in connection with present investigation.

White, J. H., Senior Surgeon. Granted one day's leave of absence en route to station, July 30, 1916.

Witte, W. C., Assistant Surgeon. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation in Cumberland County.

Young, G. B., Surgeon. Directed to proceed to Kansas City, Mo., to investigate public health organization and administration.

Births, Marriages, and Deaths

Born.

Grushlaw.—In Scranton, Pa., on Saturday, August 5th, to Dr. and Mrs. Isaac Grushlaw, a daughter.

Married.

Crispell-Schneider.—In Poughkeepsie, N. Y., on Wednesday, August 2nd, Dr. Clifford A. Crispell and Miss Georgis Schneider.

Furlong-Mauro.—In Gloversville, N. Y., on Wednesday, August 2nd, Dr. Frank C. Furlong, of Poughkeepsie, N. Y., and Miss Carmela Maria Mauro.

Died.

Baum.—In Syracuse, Pa., on Sunday, August 6th, Dr. Henry Baum, aged fifty-seven years.

Blessing.—In Sacandaga, N. Y., on Sunday, August 6th, Dr. Adam J. Blessing, of Albany, aged fifty-two years.

Buecking.—In Chicago, Ill., on Monday, July 31st, Dr. Edward F. Buecking, aged forty-eight years.

Charlton.—In Indianapolis, Ind., on Saturday, July 29th, Dr. Frederick R. Charlton, aged forty-three years.

Cheney.—In Bremen, Ga., on Monday, July 31st, Dr. I. N. Cheney, formerly of Carrollton, Ga., aged ninety years.

Cox.—In New York, on Thursday, August 3rd, Dr. Rowland Cox, of Paterson, N. J., aged forty-five years.

Fairbanks.—In Kansas City, Kan., on Saturday, July 22nd, Dr. William F. Fairbanks, aged fifty-six years.

Field.—In Indianapolis, Ind., on Monday, August 7th, Dr. Martin H. Field, aged eighty-one years.

Hickson.—In San Francisco, Cal., on Monday, July 31st, Dr. E. B. Hickson, formerly of Long Beach, Cal.

Holt.—In Chicago, Ill., on Wednesday, August 2nd, Dr. Frank Holt, aged forty-seven years.

Lackey.—In Nashville, Tenn., on Wednesday, July 26th, Dr. James H. Lackey, aged sixty-eight years.

Landis.—In Memphis, Tenn., on Friday, July 28th, Dr. Henry Z. Landis, aged sixty-four years.

Murphy.—In Mackinac Island, Mich., on Friday, August 11, Dr. John B. Murphy, of Chicago, Ill., aged fifty-nine years.

Perry.—In New York, on Monday, July 31st, Dr. Ellis B. Perry, formerly of New Bedford, Mass., aged sixty-eight years.

Snyder.—In State Line, Wis., on Sunday, August 6th, Dr. Omer C. Snyder, of Chicago, Ill.

Spenzer.—In Cleveland, Ohio, on Tuesday, August 1st, Dr. Eugene A. Spenzer, aged forty-seven years.

Sullivan.—In Bridgeport, Conn., on Wednesday, August 2nd, Dr. James L. Sullivan, aged forty-three years.

Tifft.—In New Rochelle, N. Y., on Sunday, August 6th, Dr. Edwin R. Tifft.

Webster.—In Philadelphia, Pa., on Wednesday, August 9th, Dr. John B. Webster.

Wise.—In Los Angeles, Cal., on Monday, July 31st, Dr Kenneth Wise.

Yeager.—In Philadelphia, Pa., on Friday, August 4th, Dr. William H. Yeager, aged forty-two years.

THE SUBSTITUTE FEEDING OF INFANTS.*

An Address on Its Principles and the Changes Seen During the Past Twenty-five Years.

BY J. P. CROZER GRIFFITH, M. D.,
Philadelphia,
Professor of Pedriatics, University of Pennsylvania.

No subject seems to me to offer greater possibilities of interest than the old and somewhat worn topic of infant feeding. Old it is, it is true, yet ever changing and ever new; a new phœnix of advance rising from the ashes of older consumed and abandoned ideas. Never to be completely mastered, because, whatever we may do, we are giving the infant a diet which Nature did not intend that it should have.

The fact that it is now twenty-five years since I assumed the chair of diseases of children at the University of Pennsylvania, brings before me in retrospect some of the changes and advances in the methods of feeding infants which the profession has experienced since that time. I have thought it might be of service to review briefly some of these. The amount of literature upon the subject is vast, and a consideration of all of it would fill a volume. I shall limit myself to an attempted consideration of some of the more important and practical features.

Decidedly more than twenty-five years ago the belief arose that the contamination of milk by bacterial germs was a fertile cause of digestive disturbance in early life. Scalding of the milk had long been done by the laity, although the reason was not well understood. Sterilization, continued for some time at the temperature of boiling water, had been urged and was in vogue. Pasteurization, or destruction of germs at a lower temperature, had come into prominence. These all were intended to destroy bacteria already present. They did not make bad milk good, so far as the existence of the harmful toxins produced was concerned. They merely kept it from growing worse. The first serious effort, so far as I know, toward the production on a large scale of milk bacterially clean was made by Doctor Coit, of Newark. The movement has now spread to a wonderful extent throughout the United States. In dairies supervised by medical men, with frequent examinations by chemists, bacteriologists, and veterinarians, every care is taken to produce milk which contains a negligible number of bacteria, and which is of uniform strength in its various elements. It is now no longer necessary in any of the larger cities to make use of milk which is bacterially unclean, although it sells, it is true, at an advanced price. But the movement has had more far reaching results, in that it has created a tendency toward increased care in the production of the average market milk.

At about the same time, or very soon after, came the development of the so called "percentage method" of infant feeding, advocated by Doctor Rotch; and simultaneously the dictum urged by him and others that it was the protein of the milk, especially the casein, which was the element most difficult of digestion by the human infant. These are absolutely distinct subjects and will be considered separately. Regarding the first of these, I may say that it was almost immediately recognized in this country as an enormous advance in scientific infant feeding; and even in Europe, while it did not nominally obtain this recognition, the principles underlying it practically did so, as is shown by the fact that all the very numerous special feeding mixtures devised and recommended by various foreign pediatrists were and still are constructed on a percentage composition basis.

As has been very well expressed by others, the percentage method is not a method of feeding, but a method of thinking. I would point out that we do not feed a child percentages, but fat, protein, and carbohydrate. If the food does not agree, the fault lies not with the method, but with the amounts of the food elements which we have wrongly selected The percentage method makes for accuracy to a degree which is impossible without it. No man can construct varying mixtures of milk, cream, water, sugar, and the like, without a tremendous handicap which only his special experience can overcome, unless he realizes what he is really doing in the combining of the *elements* of which the milk and cream are composed. Yet how difficult it is, even after all these years, for truth to penetrate the unenlightened mind, is shown by a recent article in one of the medical journals of this country, in which the writer criticised the percentage method as responsible for the feeding of high fats and low proteins, as had been recommended by Doctor Rotch and others. One would think it was easy to grasp the fact that

*Address delivered before a Joint Meeting of the Mifflin, Juniata, and Huntingdon County Medical Societies, of Pennsylvania, May 4, 1916.

the percentage method does not recommend *any* fixed amounts of fat or protein, high or low. It leaves that to us. It is simply an accurate way of thinking.

Much has been said about the percentage method being complicated. There is, in fact, nothing complicated about it. Let me give an instance of its simplicity. I will refer also very briefly to the manner of its employment and to its advantages. Milk is composed chiefly of three elements—fat, carbohydrate, and protein—dissolved or suspended in water. There are, of course, other elements of great importance, such as the salts, and the ferments and allied bodies. So, too, the proteins consist of more than one sort; and this is a matter of serious consideration. In the limited space at my disposal I am obliged to ignore these facts, as well as some other very important matters which recent investigations have brought into prominence. In our calculations, we consider for the most part only the three mentioned. We usually estimate the composition of average cow's milk as fat, 3.5 to 4.5 per cent., carbohydrate (in this case milk sugar), 4.5 per cent., and protein, 3.5 to four per cent. A long series of analyses made for the Milk Commission of the Philadelphia Pediatric Society gave the protein as averaging about 3.60 per cent. When we come to dilute the milk in a way to make it suitable for use for an infant, there is but little resulting error if we assume that each of the three elements is present in whole milk in the proportion of four per cent. It is not absolute accuracy of original percentages which we so much desire, as accuracy in modification. Now the whole plan of the percentage method may be made simple if we merely think of whole milk as containing fat, four per cent., sugar, four per cent., and protein, four per cent. We think of a mixture of ten ounces of milk and ten ounces of water as consisting, not of half milk and half water, but of fat, two per cent., sugar, two per cent., and protein, two per cent.; of one which has five ounces of milk and fifteen ounces of water, i. e., one quarter milk, not as quarter strength milk, but as consisting of fat, one per cent., sugar, one per cent., and protein, one per cent. That is all there is to it, and it is surely not very difficult. Now suppose we feel that one of these mixtures is too weak—as it readily may be—or that we do not have the quantities of one particular element which we wish to have; the percentage method is at hand to make us capable of mingling the elements desired in an exact manner. In our twenty ounces of mixture we determine, for instance, that we should like to have six per cent. of sugar instead of the one per cent. which the quarter dilution would give us. All we need to do is to add five per cent. of sugar, viz., five per cent. of the twenty ounces of mixture, which, of course, gives us one ounce of sugar to be added. If we fear an infant can stand no more fat or sugar, but wish to make the one per cent. protein of our quarter whole milk mixture stronger, we can do it very simply by adding skimmed milk to the mixture; for if we take the bottom eight ounces of a quart jar of milk, after standing six to eight hours, the amount of fat in it can be readily ignored. Thus if in our twenty ounces of mixture, five ounces, i. e., one quarter, of which is milk, and which, therefore, contains one per cent. of protein, we wish to make the protein two per cent., all we need do is to add five ounces of skimmed milk in place of five ounces of the water we should otherwise use. On the other hand, if we wish to increase the percentage of fat, we merely have to use a milk which is richer in fat than whole milk is. For instance, the upper twenty ounces of the quart contains approximately six per cent. of fat and four per cent. of protein. By using ten ounces of this and ten ounces of water, we have a mixture consisting of three per cent. of fat and two per cent. of protein; or if we use five ounces of this top twenty, and fifteen of water, we have one quarter of six per cent. and four per cent., respectively, i. e., 1.5 per cent. of fat and one per cent. of protein. This is certainly easy. It is no more difficult for the physician or for the mother to dilute the top twenty ounces of a quart, than it is to dilute the whole quart. If we glance at the accompanying table, which is, of course, a working table and only approximately accurate, we shall see that we do not need to employ the top twenty ounces necessarily, but can use other amounts of top milk combined with bottom milk, and can produce in different ways a large variety of combinations. For instance, to prepare this same formula containing three per cent. of fat and two per cent. of protein, we could dip off the top eight ounces of the quart, which contains twelve per cent. of fat and four per cent. of protein, and then use five ounces of this, i. e., one quarter in a twenty ounce mixture, which would, of course, cut down the proportions to three per cent. of fat and one per cent. of protein, i. e., one quarter of the original percentages present. Then, inasmuch as we wish to obtain two per cent. of protein in our mixture, all that is necessary is to add five ounces of the bottom eight ounces of the quart, which would add the needed one per cent. to the mixture.

Top and Bottom Milk Mixtures.

	Fat percentage.	Protein and sugar percentage.
Upper 4 ounces	20.	4.
Upper 6 ounces	16.	4.
Upper 8 ounces	12.	4.
Upper 10 ounces	10.	4.
Upper 15 ounces	8.	4.
Upper 20 ounces	6.	4.
Upper 24 ounces	5.	4.
Whole milk	4.	4.
Lower 30 ounces	3.	4.
Lower 28 ounces	2.	4.
Lower 24 ounces	1.	4.
Lower 16 ounces	0.5	4.
Lower 8 ounces	0.2	4.

Whatever milk we use—whole milk, skimmed milk, top milk—it is to be noted that the proportion of protein is always the same as that of the sugar. If this formula gives us two per cent. of protein, it gives also two per cent. of sugar, and we can now increase the proportion of sugar by adding that in any amount that we desire. The percentage method does not mean that we are compelled to employ cream of standard strength, top milk, skimmed milk, or whole milk. We can use any one of these which is simplest and gives us the percentages which suit the case. All that we do is to determine what percentages our patient needs, and then choose the strength milk we desire and dilute it.

As I said, that is all there is to it. It does not

take long to say, and any one with a common school education can understand it; once we have learned to think in percentages—and it is very easy—we shall never be able to think in any other way—and never want to. No matter if we are giving the baby a mixture of half milk and half water, we shall subconsciously realize that we are feeding approximately two per cent. fat and two per cent. protein.

Going back to the other matter to which I referred—the early teaching of Doctor Rotch and others of us regarding the supposed danger of a high protein percentage—the passing of time soon showed that this was to an extent an error. A number of us working independently were soon convinced that the *fat* of the food was one of the most difficult elements for the infant to digest. I remember publishing a paper upon this subject with a series of cases at about the same time that articles in the journals appeared from the pens of other teachers. The general opinion everywhere, here and abroad, is now in support of this view; and my own experience is, that by far the majority of cases of obstinate indigestion in infancy arise from the early use of artificial food too rich in fat.

Another change in our methods of feeding resulted from the recognition of the fact that the closest approximation we can make to the composition of human milk does not necessarily constitute the best artificial food for the infant. Our efforts at one period were directed to preparing a *humanized milk*—a milk mixture, the percentages of which should simulate those of human milk. We now realize that the differences which exist in the chemical composition of the various ingredients of cow's milk and human milk respectively, make the satisfactory accomplishment of this an impossibility. Few infants, in my experience, will tolerate a fat percentage in artificial food as high as that existing in human milk. This depends upon the difference in the chemical character of the fats. We have gone back, too, to the recognition of the value of a starchy addition to the food in many instances, although at one time we held that starch must not be used, because it was not one of the ingredients of human milk.

With the knowledge of the difficulty of the digestion of fat arose increased efforts to prepare a nutriment in which something else could entirely or in part take its place. Of importance in this direction was the advocacy of the so called malt soup, which, it is true, dated back to Liebig, but which was brought into prominence, as far as infant feeding was concerned, especially by Keller. Here it was found that the addition of a large percentage of carbohydrate could replace the fat to a considerable extent, and that a child would grow upon this, who had not thriven upon ordinary milk mixtures. For a reason not yet clear, it was found necessary, however, that the carbohydrates be not entirely in a soluble form, i. e., consist of sugar. A certain amount of starch was required. It was for this reason that the malt soup preparation was more efficacious and better tolerated than when merely a large amount of some sort of sugar was added to the milk mixture to make up the deficiency in the percentage of fat. The malt soup preparation may be made in various ways. Keller, using it especially in cases of difficult digestion of fat, employed one third milk and two thirds water. That is to say, he cut down both the fat and the protein percentages to about one and one third. He then made use of an extract of malt to which potassium carbonate had been added in the proportions of seven grains to the ounce, the object of this being, first, to inhibit any remaining diastatic action of the malt extract, although it was supposed to be nondiastatic; and, second, to prevent the development of an acidosis from any difficulty in the utilization by the infant of the fat still in the mixture. The simplest way to prepare malt soup is to employ one of the malt soup extracts on the market, which already have the potassium carbonate added. Following the formula for one third milk in the food, we prepare the two following mixtures: 1. Two and one half fluid ounces of malt soup extract are added to twenty-two ounces of warm water. 2. One and three quarter ounces of wheat flour (six and one half level tablespoonfuls) are added to eleven ounces of milk, stirred thoroughly, and strained through a sieve. These two mixtures are now added one to the other and boiled for a few minutes, after which the food is put into separate bottles, corked, and kept cold until needed. This gives a food containing approximately fat, 1.5 per cent., carbohydrate, ten per cent., and protein, two per cent. We notice that the carbohydrate consists partly of soluble carbohydrate in the form of maltose, dextrin, and the like; and partly of insoluble carbohydrate in the form of wheat flour. The presence of both forms of carbohydrate is considered by Keller to be imperative; and in fact, as I have said, experience seems to show that this is true. Of course, the proportions may be varied to suit the case. An increase of the milk gives larger percentages of fat and protein, while if the high carbohydrate produces diarrhea or other symptoms of indigestion, the proportions of malt soup extract and of wheat flour can be cut down. I wish to say that my experience with malt soup has extended over a good many years, and that I have found this diet extremely satisfactory in suitable cases. The high carbohydrate percentage appears to replace the missing fat to a large extent, and is, as a rule, well tolerated; and I have repeatedly had infants thrive who had done badly on all other preparations which had been tried.

In place of using the malt soup extract, we may employ any one of the good syrupy diastatic malt extracts, but it is then necessary to add the potassium carbonate, and also to boil the extract in order to destroy its diastatic properties. It will be understood that we do not desire to dextrinize the flour, but to have it remain in the food in the form of unconverted starch.

Another very successful method of feeding, which does away almost entirely with the fat, is the employment of buttermilk. This had long been in vogue, especially among the country people of Holland, but was brought into increasing prominence by Baginski and others. Buttermilk alone is rich in protein, has a reduced amount of milk sugar, and very little fat. It is, in reality, not as strong as

skimmed milk, and could not alone properly nourish an infant for any length of time. To make up for the ingredients lacking, flour and cane sugar (saccharose) are commonly added in proper proportions. The method of preparation of the buttermilk mixture, as usually employed, is as follows: Milk, best previously pasteurized or sterilized, has added to it a good liquid culture of the Bulgarian bacillus, of which there are several on the market. In from eighteen to twenty-four hours the acidulation is sufficiently advanced. It should now be stirred very thoroughly, if the milk used was skimmed milk; or churned and the butter removed, if whole milk was employed. Three level teaspoonfuls of wheat flour are then rubbed up with a few ounces of buttermilk and boiled for fifteen or twenty minutes; and, while still hot, fifteen level teaspoonfuls of cane sugar are added to this, and then the balance of a quart of buttermilk. The buttermilk mixture contains about, fat, 0.5 per cent., carbohydrate, 10.25 per cent., and protein, three to 3.5 per cent. In obstinate cases of gastrointestinal indigestion this buttermilk mixture has perhaps been of more service to me than any other one form of diet. Of course, as with the malt soup, the food must be selected to suit the case. It is adapted for infants who can well tolerate protein but fat not at all, and by whom milk sugar is also not well borne.

The employment of buttermilk showed physicians that infants could readily assimilate a high percentage of protein. This led naturally to the production of other mixtures in which the protein was in large amount, and to the construction of such foods as the casein milk of Finkelstein and Meyer. Certain other truths were at this time dawning upon the pediatric profession. Prominent here was the suspicion that it might not be the casein or the fat which was the chief disturbing element in many instances, but the whey proteids, salts, or sugar; and Finkelstein, in his first efforts, tried to eliminate to a large extent all three of these. Later it was found that sugar in some form was a requisite if the child was to gain in weight. A corollary of this was the other idea which is coming into increasing prominence, namely, that there is a synergy, so to speak, of the different elements of the food; that a certain one may be tolerated, or not when another is removed, or when something else is added. Thus in the casein milk, the fat may be found well borne, if the salts and whey proteids are reduced, and if lactose, too, is diminished or replaced by cane sugar or a dextrin maltose preparation. So, too, in the malt soup food, fat often can be tolerated if a high carbohydrate percentage is added. Again, in other conditions the presence of a large amount of carbohydrate is found to aid in the assimilation of the protein. We are only at the beginning of all that we hope to learn in this direction. Much is as yet far from being clear.

With regard to the casein milk of Finkelstein's formula, and of the various modifications of this which have been proposed; the testimony in their favor is so positive and widespread that there seems no doubt about their value. I have certainly found them of service in many instances. Yet it is only fair to say that they are difficult of preparation, especially the Finkelstein formula, and that they are often distasteful to the infant. On account of this difficulty in preparation, except by one who has had experience and training in doing it, I shall give no description of the methods employed to make the original casein milk, and content myself with reference solely to the modification proposed by Hoobler. This consists simply in the addition of a casein flour to diluted buttermilk. This increases the amount of protein, especially the casein, decidedly, while the fat is absent, the sugar low, and the whey reduced. His formula consists of casein flour, ten grams, water, one pint, buttermilk, one pint. This gives a food consisting of fat, 0.25 per cent., carbohydrate, two per cent., protein, 2.8 per cent., and with the whey reduced one half. By using soured milk made from whole milk, or by adding cane sugar or a dextrin-maltose preparation, the fat or the carbohydrate percentage respectively can be varied at will. We have used various modifications of the original formula at the Children's Hospital of Philadelphia with considerable success.

One advance in infant feeding which may be spoken of here, for the emphasis upon which we are largely indebted to Finkelstein, is that it may be not so much the action of bacteria imbibed with the milk, or present in the intestinal canal, which may be the harmful agent, but a chemical change in the food in the intestine, or faulty metabolism in the tissues, which is the chief element in the production of symptoms. Finkelstein goes so far as almost to deny to the bacteria any harmful action in the majority of instances. There is certainly a great truth contained in these views. Many of us, however, find it impossible to accept them in their entirety, and believe that bacterial action is of great importance in many cases.

Finally, I must refer to two ideas sometimes called "new," which have arisen with regard to infant feeding in the last few years. The first of these is the so-called "caloric method," which, of course, is not new. This has its very distinct uses. It is serviceable, at least in theory, for determining whether or not an infant is receiving in its food sufficient heat units to enable it to thrive. But as a method of feeding, pure and simple, it is not in itself sufficient, and probably never was intended to be. Contrasts have been drawn between the percentage and the caloric methods. No one who really understands the relationship can do this. They are not methods of feeding, but methods of calculation. Certainly any one who wishes to make the number of calories contained in the food the basis for his infant feeding, must necessarily understand the calculation of the percentages of the separate ingredients which the food contains. Otherwise he cannot, of course, calculate the calories present. An objection of moment is that the passing of time has shown us that we do not yet know how many calories per kilogram or per pound of body weight an infant really requires. Not only is there a discrepancy in the statements of investigators as regards normal infants, but it has been clearly demonstrated that it is more the body surface than the weight which determines the need; and, further, that this varies in accordance with the activity of the child, whether

awake or asleep, vigorous or weakly, and the like. Another and greater objection is that it by no means follows that one element can be substituted for another indiscriminately merely because the heat units produced in this way are the same. Naturally those physicians of experience, who have most considered and most strongly urged the importance of the caloric method, realize this full well. The trouble is that, in the hands of others, the diet may be based on calories alone, and the method became a menace rather than an aid. Of course, I have nothing whatever to say against the calculation of the caloric value of the food. I use it myself and I try to teach it to my students. It is important merely to recognize its proper place in infant feeding. The estimation of the number of calories present in the food is made very simple by the following formula, published by Fraley, which is briefly: Twice the fat percentage plus the sugar percentage plus the protein percentage, multiplied by one and one quarter time the total quantity of the food for the day, gives the number of calories present in this. Condensed it reads:

$$(2\,F.+S.+P.)\times 1\tfrac{1}{4}\,Q.=\text{Total C.}$$

The other "new" idea is the so called feeding with "simple dilutions"; meaning a dilution of whole milk with varying amounts of water, according to the case, and with the addition of sugar. Heubner, in studying the caloric needs of infants and in elaborating the "caloric method," made use of simple dilutions in this way; on the ground that the fat, being often difficult to digest, could well be replaced to a certain extent by sugar. It is very probable that this method, as advocated by him, was the basis upon which the present distorted conception is founded; this being, of course, a very different thing from the teachings upon which it is supposed to be based. The method is urged as an easy one, to be recommended chiefly because it does away with all calculations of percentages. But it is to be remembered that, as employed by Heubner and others of his calibre, a careful calculation was made of the percentages of the various milk ingredients present, and then a further calculation of the caloric values of these, and their relationship to the caloric needs of the child. There is nothing easy about this, if you wish to avoid calculations. Those who go about it in the manner we now see recommended, and who are merely looking for something easy, are by no means following the method advocated by Heubner. They have dropped their pilot, have lost their bearings, and are out of the course. There is not, and cannot be any easy method of infant feeding, except at the human breast; and even this is by no means always a successful one, as we all very well know. The "simple dilution" method as recommended by many for the reasons assigned, is only one for the lazy doctor who is trying to avoid thinking. I have a strong sentiment that the man who is not willing to take *any* amount of trouble to prepare the best possible food for an infant, had better delegate the business to some one else.

Of course, there can be no possible objection to simple dilutions. We all use them under certain circumstances, and it is certainly proper to make a food mixture in as simple a way as we can. We are at liberty to make use of well selected milk mixtures of any sort, made in any way, so long as we realize that the different milk elements can by no means be used interchangeably because they have like caloric values, and so long as we have accustomed ourselves to think in percentages, and do so think. Just so soon, for instance, as we use skimmed milk as one of the additions to our simple dilution of whole milk with water, we are in fact thinking in percentages, and are using a percentage method. Our mental process has been that we do not wish to increase the fat strength of the food; that skimmed milk contains a negligible percentage of fat; and that consequently by selecting it to form a part of the diluent, we may increase the percentage of protein and sugar without altering materially the percentage of the fat. So, too, the man who gives an infant one part of milk and three parts of water and realizes at once and involuntarily that he is feeding approximately one per cent. of fat, one per cent. of sugar, and one per cent. of protein, is feeding by percentages, and is now capable of making any mixture he may desire.

Now what mixture *is* to be desired? What will a study of the direct effect upon the infant's digestion teach us as to the changes in the food which should be made? Many things could be said in this connection, but I must limit myself to just a few practical points.

A baby unfortunately deprived very early of its mother's milk should by preference be supplied with a wet nurse. Of the superiority of human milk and of the five times greater chance of living which the breast fed baby possesses, there is no need to argue. It has been proved beyond question. If the mother's milk is merely insufficient, the baby should be allowed to get what it can, and the balance of the food should be prepared artificially. Meanwhile, every effort should be made to increase the maternal supply. If the mother's milk seems to disagree, there should be great delay in abandoning breast feeding. It often happens that after the colostrum period is well over, and the mother has become strong enough to resume her ordinary methods of life, the milk will be found digestible.

When preparing the substitute feeding for the very young infant, all the percentages should at first be low, and this applies especially to the fat. A fat percentage of one is ample, and even this is sometimes too strong. The sugar should be five per cent., the protein one per cent. Milk sugar should be tried at first, if the child is perfectly healthy; and if this is found not to agree, cane sugar or a dextrin maltose mixture may be used instead. The first effort should be to have the food agree; *not* to produce increase in weight. After the first formula is found to be well digested, the food can readily be increased to fat, 1.5 per cent., sugar, six per cent., and protein, one or 1.5 per cent. Looking again at the table of the strengths of different parts of top and bottom milk, we readily see that if 1.5 per cent. of fat and one per cent. of protein are to be used, the food can be prepared by mixing five ounces of the top twenty ounces of a quart with fifteen ounces of water, and adding sufficient sugar, since one quarter of six per cent. is 1.5 per cent.,

and one quarter of four per cent. is one per cent. If 1.5 per cent. of fat and of protein is selected, we may mix seven and one half ounces of whole milk, i e., three eighths of twenty ounces, with enough water to make twenty ounces, since 1.5 per cent. is three eighths of the four per cent. of protein and of fat contained in whole milk. Of the other ways by which the same results can be obtained, as by using both top milk and bottom milk in the same formula, I cannot take time to speak further; a little study of the table will readily show many different combinations.

Further increase in the strength of the formula will depend upon the digestion and upon the weight. No change should be made while both are in good condition. When the weight ceases to increase properly, the formula may be increased to fat, two per cent., and protein, 1.5 per cent.; and later to fat, three per cent., sugar, six per cent., and protein, 1.5 per cent., two per cent., or three per cent., provided that the baby shows a tolerance for this quantity of fat. When shall we increase the strength of the food beyond these figures? There is no rule for this. It will probably be necessary to use a stronger milk mixture as time passes; for although human milk does not increase in strength as the baby grows older, in the case of substitute feeding we are employing a diet which the child cannot utilize to the same degree, and persisting with a weak mixture necessitates giving a food which would be unduly great in bulk. What I desire especially to emphasize in this connection is that the age of the child is *in no way* to be our guide; but only the tolerance and the demands as shown by the state of the digestion and by a faithful use of the scales. I have many times seen much harm result from a too faithful following of published tables of the strength of food supposed to be required for the different months of life.

When the necessity for a substitute food first arises farther along in infancy, the same method is to be followed to a certain extent. The first formula should be very weak, although, of course, the child will not be satisfied with it or gain upon it. As soon as it is found to agree, it may be rapidly, but step by step, increased until the percentages are found to be sufficient.

So much for babies in health. What shall we do with artificially fed infants who exhibit symptoms of digestive disturbance? Some general rules may be given as a guide. Should vomiting or diarrhea develop acutely, all milk is to be stopped at once for twelve or more hours, and a purgative given. The child may be fed with plain water, weak barley water, or some other similarly harmless substance. If the condition has been hitherto constantly good, we should now work back in the course of a day or two to the previous diet. It is not necessary to make the delay very long. It is a mistake, also, to be too ready to change a formula which on the whole has been found previously to be fairly satisfactory. The frying pan and the fire are to be borne in mind in this connection.

Should the digestive disturbance be of a more chronic nature, and the child evidently not doing well, a change, of course, is needed. A wetnurse is the best remedy possible. If one cannot be obtained, there are certain pointers which show the way to the modifications of the diet which should be made. Excessive vomiting is usually due, so far as the nature of the diet is concerned, either to too much fat or too much sugar, and much more frequently the former. Either may produce sour vomiting, but the fat is first to be suspected. After a preliminary starvation and purgation, we reduce the fat of the diet greatly for a time. Here buttermilk or diluted skimmed milk is often very serviceable; and later the buttermilk mixture, with the addition of sugar and wheat flour as described. It is, however, not to be forgotten that very frequently vomiting may be brought about by other causes than the nature of the food. The child may, perhaps, be fed too often or too large a quantity, or the vomiting may be due to excitement even of mild degree, moving the body after feeding, habit, or some organic disease of the stomach, such as a chronic gastritis or pyloric stenosis.

The condition of the stools may be an indication for a change in the food. The mere occurrence of white, crumbling, or salvelike stools, is not of itself a reason for this change; and certainly not if the child is thriving. If change is really indicated, these soap stools, as they are called, depending, as they do, upon an excess of fat, may be altered by reducing the fat, or sometimes by increasing the carbohydrate in the food. Frequently malt soup or the buttermilk mixture is serviceable here, and under its use the soap often disappears, and the stools become light brown, smooth, and homogeneous. Large or small, scattered, soft, white lumps in a diarrheal stool indicate the presence of an excess of free fat. These lumps are not composed of casein, as formerly supposed; casein lumps being hard and often of a yellowish white tint. In the way of treatment, reduce the fat or increase the carbohydrate. For this purpose an ordinary milk mixture may be made which contains the ingredients in this altered relationship, or malt soup or buttermilk mixture may be employed. If the increase of the carbohydrates makes the liquid character of the stools worse, as sometimes happens, casein milk may often be given with great success. Alkaline stools, with an offensive putrefactive odor, indicate abnormal decomposition of the protein. The odor is readily recognized, and that they are alkaline can easily be determined by the use of a piece of litmus paper. Often the increase of the carbohydrates will relieve this difficulty, or giving living lactic acid microorganisms may overcome the excessive action of the proteolytic bacteria. Very acid, diarrheal stools, which irritate the buttocks and are often fermented in appearance, indicate an intolerance for carbohydrate. Abandoning milk sugar and the employment of white sugar or of a dextrin maltose preparation may relieve. If not, the total amount of sugar should be reduced. Casein milk may be of service here, inasmuch as the sugar content is low, and that of the milk sugar especially so.

There are other far more serious conditions than those referred to, one of them, for instance, that in which, with or without serious vomiting or diarrhea, the child constantly wastes. It has reached the

state of alimentary decomposition described by Finkelstein. This subject is too large for me to enter upon here. Usually nothing but the employment of human milk offers any hope of saving these children.

THE PHYSIOLOGICAL AND TOXIC ACTIONS OF FORMALDEHYDE.*

With a Report of Three Cases of Poisoning by Formalin.

By Samuel E. Earp, M. S., M. D.,
Indianapolis,
Professor of Clinical Medicine, Indiana University School of Medicine.

The aldehydes are formed by dehydrogenization of alcohols, generally by oxidation, and perhaps it is well to say that they are neutral in reaction and occupy a position midway between the alcohols and acids.

Methyl aldehyde, or formaldehyde, results from passing vapor over hot platinum or copper wire; to illustrate, $CH_3HO+O=HCHO+H_2O$.

The formaldehyde vapor is used for disinfecting rooms, but is less potent than sulphurous acid and inferior in some other respects. Its affinity for water makes it an escharotic in heavy solutions. It does not injure any fabric. However, our familiarity with formaldehyde as an antiseptic or disinfectant is perhaps generally in form of a solution which is known as formalin. This is a thirty-seven per cent. solution in water.

From the fact that it is used in several forms as a therapeutic agent it will be apropos to digress long enough to consider its physiological action in the body. The very recent publication of Mathews on physiological chemistry says that it will be recalled from the discussion of the Sorensen titration method that formaldehyde unites with amino groups to form methylene derivatives. By reduction these methylene amines can be changed to methyl amines. This seems the probable method of their formation.

It has been shown that formaldehyde is an intermediary product of metabolism in animals, but in the decomposition of the carbohydrates it is not impossible that small quantities may arise and that this formaldehyde is the source of the methylation. But this view can have no solid basis until the presence of formaldehyde in animal tissues is unequivocally established. Attention naturally turns to the two organs of the body most concerned in carbohydrate metabolism, the liver, where the carbohydrates may be formed from the proteins and stored, and the muscles, the tissues in which carbohydrate is torn to pieces and the fragments are burned for the production of muscle energy. Doctor Mathews thinks it is likely in the muscles and speaks of glycocoll which is found in large amounts in the muscles, not methylated. Formaldehyde is itself very toxic, and possibly glycocoll, which in other instances is a means of making toxic substances harmless, may also thus function in the muscles, forming sarcosine. Its possible physiological action in the body is too interesting to be left unsaid. However, the fact that it is used commercially with hardly a thought of its being harmful, is the basis for our consideration of three cases of poisoning by its use, one of which was with suicidal intent. Elsewhere we find this reference to the toxicity of formaline. On June 4, 1904, Dr. L. A. Levison, of Toledo, Ohio, reported in the *Journal A. M. A.* a fatal case in which a man took an unknown quantity of formalin, estimated, however, at two or three ounces. In 1910, in the same journal, two cases were reported; one took 100 c.c. of formalin and the other, a child, was in a serious condition as a result of inhalation of the fumes. Both recovered.

The following cases occurred during my service at the City Hospital, and careful notes were kept by Dr. Robert Moore, senior interne. Our patient seemed virtually moribund and apparently with no possibility for recovery, so that some parts of this report have the semblance of a romance. Doctor Moore not only performed the duties of interne, but those of nurse as well, and did not leave the patient for more than one hour at a time for seventy-two hours, although the regular ward nurse was in attendance. The details are as follows:

Case I. G. M., aged forty-three years, married, white, laborer. Family history, negative. Personal history: Had always been strong and healthy, never seriously sick before the present period; no operations or injuries. From my observation I estimated his weight at about 225 pounds and his height at five feet ten inches. Present condition: On March 3rd, was one of two watchers in a room where there was a corpse, and early in the morning he found an amber glass bottle which had been left by an undertaker, and drank an ounce and a half of its contents, which turned out to be formalin. His associate noticed the effect and drank a much smaller quantity. One hour later, patient was admitted to the hospital.

Examination. Patient well nourished, cyanotic and cold. Small amount of vomitus, which was thin and brown. Mucous membranes of mouth and throat dry and white in color. Temperature, 97° F.; pulse, 60, weak and irregular. Respiration, 20.

Treatment. A quart of milk was given by the stomach tube after it had been thoroughly washed by aromatic spirit of ammonia diluted, which is supposed to be the only antidote for formaldehyde. Patient was sent to ward and received a hot pack and twenty-five minims of aromatic spirit of ammonia per os, also a soapsuds enema. At 9 o'clock, when the regular bedside clinic was held, no pulse could be detected, and in the rectum the thermometer gave no register of temperature. All portions of the body were cyanotic, and the appearance of the skin reminded me of a patient with argyrosis whom I had attended at the Flower Mission Hospital. The respiration was shallow, temperature 96° F., and there was a systolic murmur transmitted to midaxillary space. Hypodermically, strychnine sulphate grain 1/30 was given. Bowels moved freely and patient vomited at intervals. Vomiting continued, with some blood in the vomitus. Two hours later, patient's temperature would not register per rectum. Twelve minims of digitalone was given. No record could be obtained of the pulse and temperature, and the respiration suggested the Cheyne-Stokes type, but the temperature and the pulse did not correspond with it. At 2 p. m. two grains of sparteine sulphate was given, also at intervals, but improvement was hardly perceptible and the betterment of conditions was not marked until 9 p. m. Dry heat was supplied constantly. On the second day, the patient rested fairly well, pulse weak and irregular, respiration slow and shallow, temperature 97° F. Cyanosis continued. The feet and hands were dark blue, also the mucous membranes, but other portions of the body were reddish and mottled. March 5th, some nausea and emesis, of light brown material, some blood.

Patient rational, but had previously been semiconscious and then dull and stupid. Liquor ammonii acetatis was given each four hours and half, an ounce of milk of mag-

*Read before the Indianapolis Medical Society, May 9, 1916.

nesia every three hours. The patient rested well the third night and accepted medication by the mouth. On the fourth day, the patient took nourishment, and while the heart murmur had disappeared, there was still marked cyanosis. Patient complained of sore throat and articulated with difficulty and then in a hoarse whisper. There was evidently edema of the glottis. Patient left on evening of fourth day without permission and, I have been told, made a good recovery.

Case II. This patient was the associate of the patient described in Case I, and took half an ounce of formalin. Very little cyanosis, and symptoms not well marked, except dry and sore throat and emesis. By stomach tube, stomach was washed with milk of magnesia, then dilute ammonia water, and later a quart of milk and two ounces of milk of magnesia were put in the stomach. Patient recovered without further treatment.

Case III. Miss S., practical nurse, aged forty years, single, white. Said she was weary of life. History of no consequence to this report, unless it be that there was a pathological connection between an infantile uterus and hysteria with melancholia. Patient was admitted to the City Hospital, September 12th, suffering from the effects of formalin which had been taken with suicidal intent. She had taken four ounces forty-five minutes before admittance to the hospital. Patient was cyanotic, temperature 96° F., respiration shallow, pulse 116, weak, rapid, and irregular. Stomach was lavaged and dilute ammonia water given, then one thirtieth grain of sulphate of strychnine hypodermically, every four hours. To relieve pain, a fourth of a grain of morphine was given one hour later. Improvement was rapid; the second and third day the urine contained albumin and sugar, which was not present on the fourth day. On account of a large amount of food in the stomach and prompt emergency treatment, recovery was gradual, with no pronounced untoward symptoms. Vomiting was easily controlled by oxalate of cerium and subgallate of bismuth, every four hours. Milk of magnesia and milk diet were included in the treatment. Dr. Joseph Wier, the interne, made note of these nervous phenomena: "Patient seemed depressed most of the time, but at other times talked freely and rapid, sometimes without reason like a neurasthenic." Before taking the formalin the patient nursed a woman who had inserted a bichloride tablet in the vagina after a debauch which had resulted in death. The depression was present afterward and she seemed to have fear of impending death and insisted that there was an unknown power urging her to put an end to her life. These symptoms, of course, did not bear any relationship to formalin poisoning, but had another pathological source; they might, however, be taken into consideration in arguing concerning the cause of the attempt at suicide.

FEVER, A PART OF THE SYNDROME OF TOXEMIA.

Vasoconstriction of the Superficial Vessels an Important Factor in Its Production.

By Francis M. Pottenger, A. M., M. D., LL. D.,
Monrovia, Cal.
Medical Director, Pottenger Sanatorium for Diseases of the Lungs and Throat.

In attempting to classify the symptoms of tuberculosis I was led to suggest that those belonging to the toxic group were, for the most part, an expression of general discharge through the sympathetic nervous system, and that they were caused by the action of toxins upon the central nerve cells. In this manner I accounted for the rapid heart's action, lack of appetite, coated tongue, deficient secretion on the part of the stomach and other glands of the intestinal tract, particularly the liver and pancreas; and for the deficiency in motility on the part of the stomach and intestinal tract resulting in slow digestion and constipation, which are commonly found as a part of the clinical expression of toxemia. I accounted for the symptoms of malaise, lack of endurance, and nervous irritability, as being parts of this same picture. I could not account at that time for fever.

Further study has led me to believe that fever too belongs to this same group; and, instead of being considered an entity, should be considered as one of the symptoms of toxemia. I do not believe that fever itself is an important factor in the production of these symptoms; but I believe it has a common etiology with them, and is a part of the general syndrome.

In order to understand the theory which I wish to advance it is necessary to review the physiology of heat regulation in the body.

Heat production depends upon the intake of food and cellular activity. The chief source of heat production of the body is muscular action. The large glands, particularly the liver, also produce large quantities of heat; but every cellular activity, except that of nerve action, has been shown to be accompanied by heat production.

The loss of heat takes place mainly through the skin, although the loss through the respiratory system is not inconsiderable. Heat is also lost by warming food and air, and some is eliminated in the urine and feces. The body temperature is also influenced by the medium in which the individual exists. If the temperature of the medium is higher than that of the body, it stimulates greater dissipation of heat, if it is lower than that of the body it stimulates greater retention of heat. In spite of all these variations, a definite equilibrium of body temperature is maintained during health. This body temperature is not the same at all times of the day, but varies with the activities of the individual. There is a daily variation of about one degree or one and a half degree, which is considered to be within normal limits. In the early morning, after the patient has been at rest during the night, his metabolic activities reach their lowest state and the temperature becomes low. At this time a temperature of 97.2° or 97.4° F. is normal. Later in the day, usually in the afternoon, when the activities of the day have reached their maximum, a temperature of 98.4° or 98.6° is attained. This natural diurnal variation of one or one and a half degree is considered normal.

The mechanism of control is so perfect that if there is an increased production of heat within the body, there is a quick response on the part of the channels of elimination, so that compensation is attained. The chief way in which compensation is reached is through elimination by the skin and the respiratory tract; consequently a greater pulmonary ventilation occurs and dilatation of the bloodvessels of the skin takes place. If, on the other hand, there is a deficiency of heat production within the body, pulmonary ventilation is lessened, the superficial bloodvessels contract, the muscles are called into action, and a greater amount of heat is produced. Shivering and chill are muscular contractions which result in increased heat production. Sometimes this greater demand for heat is met by other metabolic activities; and, if the demand is prolonged, it is met by a greater intake of food.

Departures from the normal maximum and minimum temperatures are sometimes met, of both pathological and physiological origin. When large quantities of food have been consumed we have sometimes a physiological rise of temperature, amounting usually, however, to not more than a few tenths of a degree. When excessive muscular exercise is engaged in, such as occurs in a game of tennis, or in other severe muscular exertion, the temperature will rise, sometimes to 102° and 103°. This physiological rise of temperature is quickly followed by increased respiratory effort, dilatation of the capillaries of the skin, sweating, and a restoration of the normal heat equilibrium. It is not accompanied by symptoms other than those which occur from a feeling of excessive warmth. A pathological rise of temperature, on the other hand, is different, and when it occurs the normal is not so quickly restored. It is accompanied by other symptoms which, when taken together, we recognize as the syndrome of toxemia. The syndrome differs in acute and chronic infections, and also according to the severity of the toxemia. The syndrome seems to be due to central action upon the nerve cells.

The symptoms of toxemia, as I have studied them in tuberculosis, would be the same for all infectious diseases and all experimental toxemias, differing only in degree, as the disease is acute or chronic, or as the toxemia is slight or severe. They are as follows: Malaise, lack of endurance, loss of strength, nervous instability, headache, general aching, lack of appetite, digestive disturbances, loss of weight, rapid heart action, night sweats, fever, and anemia.

When toxemia is very severe, on the other hand, producing collapse, there result: Vasodilatation (vasomotor paralysis); sweating; and subnormal temperature.

This study leads me to suggest that fever, like the other symptoms of the syndrome, is due to sympathetic stimulation, as I shall attempt to explain.

Pyrexia may be caused, as seen from the physiological facts mentioned above, either by increased heat production or interference with heat elimination. That the chemical action which takes place within the body as a result of increased metabolic change on the parenteral introduction of bacterial protein into the body or through infection, should be accompanied by the amount of heat production required to raise the body temperature to the heights where we find it in cases of the ordinary infections, seems decidedly questionable. This seems all the more improbable if the heat dissipating mechanism is not interfered with; because such physiological rises as accompany severe muscular exercise are quickly relieved by increased pulmonary ventilation and dilatation of the skin vessels causing a temporary increase in heat loss.

If we further study the phenomena which accompany toxemia, we shall see that there is an indication of interference with heat elimination. During the early hours when fever is coming on we find vasoconstriction in the superficial tissues and a tendency to chill. Vasoconstriction is further shown by such experiments as those reported by Jona,[1] in which he noted that after the injection of protein into a rabbit, vasomotor disturbance was manifested by constriction of the vessels of the rabbit's ear. Thus we are led to believe, both from our clinical observation and experimental study, that vasomotor constriction of the bloodvessels of the skin is an effect of toxemia; and, from this, we can account for the rise in temperature, even without a great amount of chemical change within the body. That there is some increase in heat production is unquestionable, but that there is a sufficient amount to cause the rises which we often see following the injection of an infinitesimal amount of protein seems improbable. For every degree of rise in temperature a ten per cent. increase in body heat is required. I have seen a rise of 4.5° follow two mgs. of old tuberculin. It does not seem possible that such a dose could stimulate the production of an amount of heat equal to forty-five per cent. of that of the normal body; it seems far more probable that an interference with heat dissipation is the important factor.

We are further led to suspect this action from the fact that toxins and adrenine act in the same way. Adrenine will produce a general vasomotor constriction when injected into the blood stream in extremely small doses. It will also cause increase in body temperature.

It has been shown by Vaughan, experimentally, that raised temperatures simulating the various types met with in clinical medicine may be produced by injections of foreign protein, the type of temperature depending upon the method of dosing. One single injection is followed by a rise and a fall to normal. A continuous series of injections is followed by a continuous type of fever. This can also be altered so as to give either the remittent or sustained type. The explanation would be that the toxic action of the protein expending itself upon the sympathetic nervous system produces stimulation of the vasomotors of the skin, and then, as soon as the protein is destroyed, the vessels return to normal; with a resulting equilibrium in heat production and heat elimination. When repeated doses of protein are given at frequent intervals, the stimulation of the sympathetics is continuous; a constant vasomotor stimulation results; and hyperpyrexia is continuous.

In this way we can also account for the fever which follows various depressive emotional states. We have all seen a rise of temperature follow discontentment, worry, anxiety, discouragement, fear, and other similar states; but we have heretofore been unable to explain them. Recent physiological investigations show that the action of such depressing emotions is manifested upon the sympathetic nervous system. Along with other manifestations we find that of vasomotor stimulation, interfering with heat dissipation. That this is the probable explanation, is also evidenced from the physiological fact that nervous discharge is not accompanied by heat production, consequently, disturbances in heat elimination, rather than heat production, must be the important factor in the production of fever.

We have been inclined, particularly in chronic fevers, to consider that there is some disturbance of the heat centre. A heat centre has not been

[1] J. L. JONA: A Contribution to the Experimental Study of Fever, *Journal of Hygiene*, XV, 2, 1916.

proved to exist; in fact, there is considerable doubt whether such a thing would be consistent with the great number of agencies which are present in the organism to produce heat and cause its loss. Bechtrew[2] and Starling[3] both express considerable doubt on this point, and say that it is nothing more than an assumption.

This theory of the action of fever greatly simplifies our symptomatology in infectious diseases. It shows that fever is not an entity and that we should not characterize periods of activity in infections as the "fever stage".

Fever is only one symptom of the general syndrome of toxemia; and, like the other symptoms, is due to the action of the toxins upon the nervous system. It arises largely from constriction of the superficial vessels interfering with heat dissipation. Its production is a part of a general sympathetic stimulation. The collapse which results from excessive toxic action is due to a vasodilatation, a temporary or permanent, vasomotor paralysis, and is accompanied by perspiration, rapid dissipation of heat, and subnormal temperature.

TYPHOID FEVER.

Two Unusual Cases.

By I. L. Nascher, M. D.,
New York.

The following cases are reported because they possess unusual features. The first was irregular in its onset and course; the other was peculiar throughout and taken with the remarkable findings upon autopsy may be unique.

Case I. Mrs. E. N., aged forty-nine years, weight 270 pounds, a heavy eater, with three or four stools a day. On the night of July 28th, she had a chill, followed by fever, headache, diarrhea, nausea, cough, but no expectoration. She said she had been feeling bad, not exactly sick, but not as bright and active as usual for two weeks, but this malaise she ascribed to the heat; now she felt sick all over. A few hours after the initial chill she had a temperature of 104.6° F., pulse 120, respiration 30. The respirations were shallow, face flushed, eyes injected. It resembled the onset of lobar pneumonia. She complained of pain all over, head, chest, back, abdomen, limbs, wherever I touched her or questioned her about. Owing to a thick layer of fat it was impossible to get physical signs of pulmonary trouble, and for the same reason it was impossible to reach the spleen at any time during the disease. As in all these very obese cases, the ordinary diagnostic measures and methods were of little use and we had to depend upon the history and instrumental measures. In this case the abdomen was not distended, and there was no marked tenderness aside from the general discomfort which she described as pain, except along the scar of an old operation for hernia and lipectomy. She had several stools on the 29th, but this was not unusual, and as there was no other symptom which would lead to a diagnosis of typhoid fever, and there were symptoms which would indicate a lobar pneumonia, this provisional diagnosis was made. Under quinine and phenacetine the temperature dropped to 102.6° F., in forty-eight hours, but neither bismuth subcarbonate or subgallate, opium or tannalbin had the slightest effect upon the diarrhea. The temperature was irregular during the first five days, ranging from between 102.6° and 104.6° F., dropping after the administration of the antipyretic and rising again in a few hours. The absence of pain in the chest, the subsidence of the cough, the absence of expectoration, and the persistence of the diarrhea, which toward the end of the week became watery, led to the suspicion of typhoid. There was dulled intellect, which was ascribed to the opium, but this persisted for three weeks. The headache had disappeared after the first day. On the sixth day a Widal and a diazo were both negative, and on the following day an expert diagnostician gave the guarded diagnosis, gastrointestinal intoxication, possibly typhoid. The stools were beginning to have a fetid odor; they were liquid with soft yellowish lumps, small in quantity, but passing eight to ten times a day. From this time on the case was treated as one of typhoid. On the sixteenth day another Widal gave an incomplete agglutination and diazo again negative. Although textbooks say there is no eruption after the fourteenth day, in this case the typical typhoid spots first appeared during the third week, were first seen upon the arms, and two days later appeared upon the abdomen. Delirium occurred on the twentieth day and for a few days thereafter. There was little abdominal distention at any time; the greenish, pea soup diarrhea appeared about the end of the second week and continued for ten days, and the severe typhoid state began with delirium and lasted about a week before there were signs of improvement. The mind cleared up rapidly, appetite returned in a few days, but strength returned slowly. The patient went out on September 1st, and for several days thereafter, but on September 7th there was a mild relapse lasting two weeks.

On September 5th, the nurse and the patient's son, aged seventeen years, showed the initial symptoms, and on September 12th a daughter was taken ill. There were no unusual features in the cases of the son and the nurse, and they recovered.

Case II. H. N., daughter of foregoing patient, aged thirteen years, weight 170 pounds, looked like a girl of eighteen. Received a dose of typhoid vaccine for immunization on September 8th, which produced no reaction. On September 12th, she complained of headache and chills, had a vomiting spell, and went to bed. The disease had a fairly typical course; the highest temperature was reached on the 23rd (104.6° F.), reached normal on September 29th, and a few days later the girl was allowed to leave the bed and see visitors. During the illness a Widal and a diazo were positive. On the evening of October 10th, after seeing several friends, she said she did not feel well, but there was little change in temperature or pulse rate until the 12th. At 4 p. m. of the 12th, the temperature was 99.4° F., pulse rate was 93, respiration 20. At midnight of the 13th, the temperature was 102° F.; the pulse rose to 145 on the morning of the 14th, and to 160 at noon on the 15th; respiration rose to 30 at 4 p. m. of the 15th, and to 48 four hours later. On the 15th, Dr. Robert Abrahams was called in consultation and found areas of percussion dullness and other signs of pulmonary involvement, although there had been no chill, cough, pain, expectoration, dypsnea, nor any of the usual symptoms of pneumonia. On the evening of this day the heart sounds were weak and irregular, respiration sometimes deep and full, at other times shallow; the abdomen was distended, but there was no tenderness. The face was pale, expression dull, and the patient was very restless. The stools, which had been normal for a few days, again became thin, small, and frequent. Widal and diazo positive.

From this date, October 15th, to the date of death, December 12th, a brief résumé of the progress of the disease each week will be given. It should be noted in the figures that there is no relationship between temperature, pulse, and respiration, that frequently one would rise and the others fall, or there was marked rise or fall in one and no corresponding rise or fall in the others. The rate of respiration, when sleeping, was from 8 to 15 less than when awake, but when her attention was attracted and she found that the rate of breathing was observed, she breathed more slowly. On one occasion, when counting the respirations by placing the hand upon the chest, the rate was 28, and a few minutes later when it was taken unobserved it was 44. The pulse rate was always lower during sleep and very slight causes sufficed to raise it from 5 to 15 beats a minute. There was frequently a marked rise or fall in temperature, pulse, or respiration, without any apparent cause.

First week, October 15th to 21st. The temperature range was 102.4° to 105° F., the latter reached on October 19th, at 12 and 4 p. m. Pulse range 120

[2] *Die Funktionen der Nerven*, 1908.
[3] *Principles of Human Physiology*, 1915.

to 164, the extremes occuring within ninety minutes on the morning of the 20th. Respiration ranged between 38 and 60. The particular features were the restlessness with occasional delirium, frequent abdominal distention relieved by colon irrigations and turpentine enemata, the return fluid being always thin, yellow, without odor; a persistent weak pulse notwithstanding heroic doses of the ordinary heart stimulants. The area of percussion dullness over the lungs had increased during the week, the respiration was occasionally labored, there were two short periods of cyanosis, but the usual symptoms of pneumonia were absent.

Second week, October 22nd to 28th. Temperature range 101.8° to 104.2° F,; pulse, 102 to 158; respiration, 40 to 54. On October 23rd the pulse rate was at midnight 128; at 4 a. m., 102, and at 8 a. m. 130. During this week the symptoms were mainly cerebral and intestinal. She was always restless, occasionally delirious, passed stool and urine unconsciously. Abdominal distention was frequent, requiring colonic irrigation, turpentine enemata, and stupes.

The return was always a thin, yellow fluid, much flatus, and occasionally some semiformed feces. On October 25th patient expectorated some dark brown sputum, but had no other pulmonary symptoms. Percussion was not quite as dull at the end of the week and apparently diminishing in area. The patient complained once of pain in the heart and several times of distress in the abdomen when distended. On the afternoon of the twenty-fifth her face was flushed for several hours.

Third week, October 29th to November 4th, temperature range 101° to 104° F.; pulse, 124 to 168; respiration, 34 to 56. On November 2nd there was a sharp drop in respiratory rate from 54 to 34 in eight hours, and a fluctuation in the temperature rate of three and a half degrees in a few hours. During this week the cerebral and intestinal symptoms continued, but gastric symptoms became pronounced. There was frequent nausea, occasional vomiting, an erratic appetite. Respiration was frequently labored, generally shallow, an occasional cough, but no expectoration. On the morning of November 3rd the respiration was labored and about 3 a. m. there was a spasmodic fit of coughing followed by the expectoration of some white mucus. Later I found some rales and friction sounds in the chest. The pulse rate after the coughing spell was 168, hardly perceptible. Two hours later, it had dropped to 130. The patient complained of headache, earache, and various other pains and aches during the week, but at the end of the week she appeared stronger and brighter.

Fourth week. November 5th to 11th. Temperature range was 100.4° to 103.8° F.; pulse, 110 to 164; respiration, 28 to 48. On the seventh there were several sharp fluctuations, temperature between 100.4° and 103.2°; pulse between 110 and 148; respiration, between 28 and 44. The cerebral and intestinal symptoms were milder, but the gastric symptoms were more severe. She was still restless at night, but there was no delirium and she was bright during the day. There was little abdominal distention, stools were more often semiformed and not so frequent, and irrigations and enemata were unnecessary. One day, a few small doses of a calomel brought a thin, green, offensive stool, but the next was normal. Vomiting was now more frequent, the vomitus containing bile, mucus, and food. There was an absence of pulmonary symptoms aside from the character of the respiration, but physical signs were more marked than during the previous week. There was dullness on the right side, flatness with change of level on both sides, friction sounds, but no rales. The pulse was generally weak, becoming dicrotic on the morning of the ninth; later in the day it was irregular. On November 9th a painful swelling appeared on the left thigh, at the spot where frequent hypodermic injections of camphor in oil and other drugs had been made. Hot poultices, boric acid solution, and tincture of iodine were applied and an abscess was opened on the morning of the thirteenth. At the end of the week the temperature was generally lower, but the patient was not as bright nor as comfortable as at the end of the previous week.

Fourth week, November 12th to 18th. Temperature range, 100.2° to 103.8° F.; pulse, 102 to 152; respiration, 34 to 48. On the sixteenth the temperature range was between 101.2° and 102° F., pulse between 122 and 140, and respiration 34 and 44. On the following morning there was a drop in the pulse rate from 134 at midnight to 102 at 5 a. m., and a rise to 140 at 8 a. m. On the morning of the thirteenth the abscess opened and discharged a large amount of thick, stringy, greenish pus. The abscess formed a cavity in the fat, over one inch deep and one third inch wide. Under antiseptic irrigations, aseptic dressing, and drainage, the discharge diminished. After the fifteenth, when a mass of necrosed fat tissue was discharged, the drain when removed showed only a reddish serum or a small amount of pus; some days it contained nothing and it seemed that the wound was healing.. During this week the cerebral, intestinal, gastric and pulmonary symptoms were aggravated. The patient complained of frequent headaches, was generally restless at night, and was frequently depressed. The stools were sometimes a yellow liquid, sometimes a yellow soft mass, generally with a foul odor; there were from five to eight passages daily. No abdominal distention was evident, but some tenderness on pressure below the umbilicus. The gastric symptoms predominated. The patient frequently complained of nausea, and vomited a thin, yellow fluid which had a sickening odor. Lavage on the seventeenth had no result, the water being returned unchanged. Milk was generally retained, but other food was returned, either in a few minutes or after an hour or two. On the evening of the sixteenth the patient complained of pain upon breathing. Examination next morning showed pleuritic effusion on both sides. Still there was no cough, dyspnea, distention, or expectoration that might be expected with pleurisy, and the pain was rather an ache and not the sharp, sticking pain usually associated with this disease.

Sixth week, November 19th to 25th.—Temperature range, 100.6° to 103.2° F.; pulse rate, 136 to 152; respiration, 32 to 50. There was a fairly regular daily fluctuation of two degrees, and the pulse and respiration fluctuations were also fairly regular. It was a typical septic temperature, but many of the symptoms were present from the beginning of the

relapse and were undoubtedly due to the typhoid infection. There was still great restlessness at night, while during the day the patient was sometimes bright, at other times dull or depressed. The stools had a foul odor, but otherwise resembled the stools on the fifth day of the relapse. The pulmonary symptoms were more pronounced, there was more pain in the chest, and considerable pain upon percussion; there was also some cough, but no expectoration. The predominating symptom was the persistent vomiting. The vomitus was a yellow or a greenish yellow fluid, alkaline in reaction, and containing mucus. The food during this week consisted almost exclusively of fluid and evaporated milk, and this was generally retained. Occasionally there were some flakes of milk curds. The patient was weaker this week. Widal and diazo taken this week were positive.

Seventh week, November 26th to December 2d. Temperature range, 100.4° to 103°; pulse 124 to 148, respiration 24 to 40. The daily fluctuations were slight. On November 28th the extreme range of pulse was 132 to 142, and respiration 32 to 36. The wound discharged very little pus, and was apparently becoming smaller. The vomiting of yellow fluid continued, and on the twenty-ninth the patient vomited a thin, acid fluid, not as yellow as the usual vomitus. Some foods caused nausea and were immediately vomited, but others that she liked were retained. As she was getting weaker it was necessary to increase the amount of food, but an increased food supply caused increased vomiting and diarrhea. The stools were still soft and yellow, and some were free from odor. On the 30th the patient passed a brown, partly formed, semisolid stool, the most normal since she had the relapse. On the following day, there was a discharge of pus from the rectum, and a few hours later a return of the soft, yellow, fecal discharge, covered with pus. There had been no symptom indicating perforation of the bowel, and the only conclusion was that an intestinal abscess had opened. During the week the cough increased, there was some expectoration of mucus, and one day a copious expectoration of frothy white mucus. There was still some pain in the back, but she complained of considerable pain in the joints. She was cheerful and bright, and not so restless at night.

Eighth week, December 3d to 9th. Temperature range, 99.8° to 103.6° F.; pulse 124 to 144, respiration 20 to 42. At noon of the sixth the temperature was 99.8°, pulse 124, respiration 24. Four hours later these had risen to 103.6°, 144, and 42 respectively. The vomiting continued, the vomitus being sometimes a yellowish, sometimes a greenish fluid, which toward the end of the week had a foul odor; a similar foul odor came from the mouth. Some food was retained, but most was vomited after a few hours, generally in process of digestion. The stools during the week were generally thin, yellowish, or greenish; occasionally there were partly formed, brown feces and sometimes a small amount of free pus. On the afternoon of the 8th the nurse noticed pus oozing from the vagina and that evening pus was found to come out of the vagina during a bowel movement. I found the following condition on the ninth: The wound was still discharging a small amount of pus. The patient complained of pain from breathing and coughed up a considerable amount of white frothy mucus and some thick greenish mucus. There was percussion flatness on both sides, friction sounds on the right, a few large moist rales front and back. She vomited a thick, greenish fluid, containing pus, bile, and mucus. While she was straining at stool, pus oozed from the vagina, the feces were covered with pus, and some pus dripped from the rectum after the feces passed. The right foot had become edematous and she complained considerably of pain. It seemed evident that there was now a rectovaginal perforation or a pus pocket in the cul-de-sac which had opened into the vagina, and the pressure at stool may have squeezed some of the pus in the pocket into the vagina. She was very weak, but cheerful. During the afternoon I sent her to the Jewish hospital in Brooklyn with the faint hope that a laparotomy might save her. In the hospital she could retain no nourishment, continued to grow weaker, became comatose on the afternoon of the eleventh, and died on the morning of the twelfth.

The autopsy report was as follows:

Name, H. N., Autopsy, *December 12, 1915.*

Young female, well nourished, well developed, looked eighteen years old, was thirteen; five feet six and one-half inches tall.

Skin. On posterior surface above right ilium are a few areas 2.5 by three cm. in length, of a color simulating a burn healed. Similar condition about each knee. Skin felt doughy. On the upper and outer aspect of left thigh were two circular areas—the upper one exhibited the subcutaneous tissue—the lower one a sinus which extended upward and inward for about five cm. Slight edema of lower extremities half way up leg, more marked on right side.

Pupils equally and moderately dilated. Mucous membranes very pale. Cervical glands not enlarged. No glandular enlargement. On section subcutaneous fat was yellow, about two cm. thick. The intercostal muscles were light pink. Subcutaneous fat over abdomen about four cm. thick. On opening abdomen there presented to view the transverse and ascending colon, cecum, and a few coils of small intestine. Omentum was thin and extended a little below umbilicus. Small areas of whitish color over peritoneum of transverse and ascending colon and all over omentum (fat necrosis). The transverse colon in left hypochondrium was adherent to parietal peritoneum. On breaking through adhesions, a large cavity was present which extended to dome of diaphragm. The adhesions extended to epigastrium and right hypochondrium and over liver, but did not present a continuation of the cavity described. The hepatic flexure of the transverse colon was adherent to inferior margin of liver and on breaking through adhesions, a cavity, which was continuous with the cavity described, was found. The adhesions between ascending colon and posterior parietal layer were intimate and on separating them there presented a necrotic membrane full of openings (artificially made) through which a large amount of greenish brown material (pus) exuded. In other words, the posterior surface of ascending colon was necrotic. The appendix showed congestion. Scattered throughout mesentery and on the surface of loops of small intestine, were small necrotic areas as described before.

Chest opened. Eighty to one hundred c.c. fluid in pericardium; retrosternal glands were not enlarged. Left pleural cavity completely obliterated by fragile adhesions. On reaching the level of the fifth rib, breaking the adhesions caused a gush of pus, the source of which was traced to an opening in the diaphragm communicating with cavity described. The right pleural cavity was partially obliterated by adhesions along the base that were easily broken through. On right side the diaphragm reached the fourth

rib. On left side indeterminable. There was a pleuropericarditis on left side. No persistent thymus.

Heart. Surface, pale pink. Small amount of fat. Lower lobe of left lung intimately adherent to diaphragm and separation revealed necrosis of diaphragm and presence of an irregular opening connected with cavity described. On separating parietal pleura, to which dome of diaphragm was adherent, a few large necrotic areas were seen. Spleen intimately adherent to parietal peritoneum and tissues bounding it. Inner surface of spleen was left border of cavity. Upper surface of cavity was formed by diaphragm and posterior surface of stomach. Stomach contained a small amount of thick brown bile stained mucus. Rugæ were normal; numerous punctate hemorrhagic areas throughout. Duodenum normal. Pelvis clear, with the exception of a few necrotic areas as above described. Liver weighed five and three-quarter pounds, enormously enlarged, especially right lobe, pale, yellowish pink. Left edge of left lobe formed part of right edge of necrotic cavity. Right kidney was moderately enlarged, lower half of posterior surface and inferior pole was adherent to posterior structures. That part of retroperitoneal cavity on right side below the margin of floating ribs presented the lumbosacral plexus of nerves imbedded in necrotic tissue. Left kidney slightly enlarged, posterior surface adherent to posterior abdominal wall by necrotic adhesions. On right side the transverse processes of second and third lumbar vertebræ were denuded.

In reviewing the clinical history, we are struck by the persistence of the four groups of symptoms, gastric, intestinal, pulmonary, and cerebral, the frequent absence of correspondence between symptoms and physical signs, and the improvement in the cardinal signs, temperature, pulse, and respiration, toward the end.

The cerebral symptoms included restlessness which persisted throughout, delirium during the first two weeks, and hebetude frequently thereafter. The mental attitude changed as rapidly as the pulse and at times the patient said she felt perfectly well and wanted to get up and be dressed. Perhaps within an hour she would be dull and irritable, and moan without having any pain. She was generally depressed after vomiting, but not after stool. The signs of pulmonary disease were discovered on October 15th, but aside from the labored breathing occasionally and an infrequent short cough or rather a hack, there were no marked pulmonary symptoms until the fifth week. The symptoms and physical signs did not correspond at any time.

Anorexia and nausea began during the first week, vomiting during the third week, and this became the most pronounced symptom during the last three weeks. There was little change in the character of the vomitus, except that toward the end it had a foul odor and afterward contained pus. The diarrhea persisted from the beginning and did not change in character, except toward the end when it had a foul odor and contained pus. For several days at the beginning it was necessary to give frequent colonic irrigations to relieve the flatus, but the stools as well as the return from the irrigations were like the yellowish, thin, fecal movements of the eighth week. Some stools toward the end were more formed, darker, and harder than others, and it seemed that she was improving when pus appeared in the stool and it again became thin, yellowish, and foul. The greatest danger appeared during the first three weeks, when the pulse was frequently imperceptible. The pulse was weak and irregular after this time, but it always responded rapidly to hypodermic injections of camphor, digitalin, strychnine, brandy, or other cardiac stimulant. Whiskey was given throughout the disease; digitalis was given frequently and during the last week in half dram doses; dilute hydrochloric acid was given for six weeks with occasional intermissions. Other drugs were given when indications for their use arose, but most were vomited after the third week. Vomiting was controlled for a short time by cocaine, but when its action ceased the patient vomited more than before. Bismuth subgallate, tannalbin, and similar intestinal astringents temporarily controlled the diarrhea, but this was followed by abdominal distension. Neither hexamethylenamine, salol, nor the sulphocarbolates had any effect upon the character of the stools when they were foul smelling, nor was charcoal of any use for the stomach or intestines. The patient responded to drugs given *per os* during the first three weeks, afterward few drugs produced any impression unless given hypodermically. Under atropine given hypodermically the respiration improved when it was so shallow as to be barely perceptible, and the girl was cyanosed.

The question of vaccine treatment was considered. Here were two and perhaps three distinct infections, typhoid, pneumonic, and septic. The first was the primary and until late in the disease the predominating infection, and typhoid vaccine had so far been ineffective. This line of treatment was therefore considered inadvisable. Until it became evident that there was a severe septic infection, the outlook for recovery under the treatment was favorable, and it was decided to continue with drugs, diet, and careful nursing. In this I was supported by several physicians who saw the case. The autopsy, made a few hours after death by Doctor Blatteis, pathologist of the Jewish Hospital, revealed an extraordinary state of affairs, but it did not clear up some of the essential points in the clinical history.

The remarkable points in this report were, a pus reservoir lying between the transverse colon and the diaphragm; perforation of the diaphragm upward into the pleural cavity; no pathological condition of the lungs, except adhesion of the lower lobe of the left lung to the diaphragm; the widespread adhesions and necrotic areas; the denuded lumbar vertebræ; the absence of perforation of the vagina or other assignable cause for the presence of the pus in the vagina; the enormously enlarged liver. The clinical history and the autopsy findings were so greatly at variance that it was impossible to harmonize them except at a few points.

The Value of Radium in Pelvic Cancers.—Henry Schmitz (*Surgery, Gynecology, and Obstetrics*, August, 1916) with respect to the above matter summarizes as follows: 1. The therapeutic action of radium depends on a correct technic, which must be based on a careful physical examination of each patient. 2. The results of radium therapy in inoperable and recurrent cancers surpass those of any known therapeutic agent. 3. The prophylactic use of radium in operable cancers increases the percentage of operability and probably the efficacy of the operative procedure.

THE GENERAL PRACTITIONER.

By J. V. O'Connor, M. D.,
Woonsocket, R. I.

For some time it has been the practice of a few of the so called leading medical men, to make use of various newspapers and medical journals in which to criticise the general practitioner of medicine. One author in particular has gained a great deal of notoriety; several of his articles have come under my observation and have served to lessen my former admiration and respect for him.

It is amusing to read a statement which says that the practising physician receives too great compensation for his services. I wonder if the writer of this sort of literature is familiar with the income of the average physician. A statement like the foregoing does not call for contradiction. All I suggest is that any one possessing such an opinion need only refer to statistics, when it will be seen that the physician, in most cases, is underpaid. Personally I do not believe that the author of the articles which I have read ever thought for a moment that his personal fee for office visits or consultation was exorbitant. Perhaps some of us who know of certain fees received, feel that in some cases he may have been overpaid. Of course, in his capacity as an internist, with his reputation and social standing, he may be entitled to enormous fees.

If the physician must write a word regarding his fellow medical man, let him begin by saying that, as a rule, the general practitioner is a conscientious person whose numerous works of charity are often unheard of and whose death is often premature, owing to hard work and worry over patients under his care.

I have often discussed the financial situation with brother practitioners, and it is a common thing to hear the remark, how poor their collections are and how difficult it is at times to make both ends meet. It is an easy matter for our friend, the author, to write articles casting ridicule upon his brother doctors. How nicely he informs the public that they are dealing with a lot of pill peddlers, whose knowledge is very limited, and that the only place where patients are properly cared for is the hospital. Again I beg to differ with our worthy specialist; a great majority of general practitioners know very well what they are doing. They are posted regarding their profession, especially those who have graduated during the past eight or ten years. They can make a first class physical examination, and, if necessary, can do a blood count, absolute or differential. They can thoroughly examine urine, quantitatively or qualitatively, and if need be can extend their knowledge a little further and do a gastric analysis.

While I will admit that hospitals are indispensable, I must also hold that a good home is far more acceptable to the patients. The patients prefer the home in a great majority of cases, and if they have the advantage of proper hygienic conditions, including good nursing care, they will do as well as, if not better than in the hospital. There are many medical cases sent to the hospital that would be better off at home under the observation of the family physician.

To go back to the income of the physician, it might be well to remember that the large fee often charged by the specialist is, in a measure, responsible for increasing the average income of the physician, on paper. Compare the average income from the earnings of the general practitioner who does nothing but general work, and you will find that they are fortunate if they obtain a good living wage. It is a fact that a large majority of the so called "big" men, particularly those doing office, consultation, and hospital work, are prone to look upon therapeutics as a very small matter. The author of the articles which I have read has the reputation of being a therapeutic nihilist. Medical treatment in most cases amounts to nothing. We all know that diagnosis is the keynote to success, but what comes after diagnosis? Just because the mortality in lobar pneumonia is twenty-five per cent., is that any reason why treatment is contraindicated? A therapeutic nihilist tells you that the mortality is twenty-five per cent., no matter what the treatment is. That is something that I do not believe. I have seen patients suffering from lobar pneumonia who would have died had not the "pill peddling" family physician stayed with them for hours and administered the very necessary stimulation as indicated. Personally I have had cases, one in particular, where it was necessary for me to stay with my patient many hours at a time for several days. Attacks of respiratory failure occurred often, twice he had an acute dilatation, and the crisis did not occur until the thirteenth day. At all times the patient responded to powerful stimulation, and there is no question in my mind that the patient would have died long before the crisis if he had not received symptomatic treatment whenever it was indicated. Of course, the question of stimulation is one worthy of no little attention. I believe that many patients are stimulated long before it is necessary, and therefore fail to respond when it is really needed.

At times the therapeutic nihilist may not favor surgical treatment, even if results seem to be all that are desired. I know of a very prominent internist (an author who has written more than one undesirable article regarding the general practitioner) who will tell you that the operative treatment for exophthalmic goitre, while mechanically correct is physiologically wrong, and for that reason he is somewhat skeptical. We all know that whether it is or is not physiologically wrong, we get results that are really good, and shall continue to approve of the surgical treatment in many cases. This particular diagnostician showed no interest in the treatment of exophthalmic goitre. The only thing that seemed to interest him was the diagnosis. He had absolutely nothing to offer, only rest and plenty of it. We acknowledge that rest is often essential, and in some cases seems to produce excellent results, but how often it fails.

To go back to the use of drugs, the therapeutic nihilist will very readily use quinine, potassium iodide, mercury, or iron. He will admit that good results are obtained when these drugs are used in their respective indications, but at the same time he will scoff at the practitioner who lays claim to results from numerous other drugs. It is quite un-

natural to suppose that there are only half a dozen drugs in the world that are of any value. We have found quinine to be a most valuable drug. Originally some one told us that it was, and after using it we became convinced. So it is with many other drugs, and while I do not boast of using an enormous variety, those that I do use have proved satisfactory.

In my opinion the capable practitioner is he who can make a diagnosis, and if necessary give a legitimate reason for making it. He has a good knowledge of therapeutics. Making a diagnosis should be the object of every physician, but after that do not forget that symptomatic treatment is beneficial to your patient, often relieving the strain and helping him to get well. What would the practitioner of medicine have to offer, if, after making a diagnosis, he did comparatively nothing to help his patients?

In conclusion, I will repeat my statement, that for proper care and treatment the hospital is not always required; that the average general practitioner, with his therapeutic knowledge and his many acts of charity, is doing an immense amount of good. He is not a peddler of pills, but a hard working, conscientious man, who should in many cases receive more financial remuneration from those who can afford it than is now the case.

71 Main Street.

AN EVALUATION OF PARAPHRENIA.*

By Edward A. Strecker, M. D.,
Philadelphia,
Assistant Physician, Pennsylvania Hospital for the Insane.

(*Concluded from page 349.*)

The following case also stands out prominently from a large amount of chronic paranoid material, chiefly by reason of retained equilibrium of affect life and the minor amount of damage, if any, to the function of the will.

Case II. M. C., aged fifty-seven years; duration of psychosis at least eighteen years. Original diagnosis, chronic melancholia. In this case there had been the gradual development of fantastic but fairly closely coordinated delusions of persecution. Hallucinations of hearing and sight and finally of all the senses were the avenues through which the conspirators gained access to their victim. Occasionally, however, the visual falsifications partook of the grandiose and were in the nature of special revelations. In later years, too, there had been the development of a feeling of confidence and power on the part of the patient, a growing belief that after all he was to prevail over his enemies. All things considered, the reaction to the system of persecutory ideas had been fairly adequate. Once the patient attempted suicide to escape his pursuers. There had been no diminution in the delusional conceptions; indeed they seemed to wax stronger and if possible were elaborated with more detail.

The affect life is and has been strikingly different from what we should naturally expect to find in the chronic paranoid dementia præcox type of even the most gradual evolution. The onset of the psychosis was marked by a fairly well defined depression and there have been phases of emotional excitement scattered through its course. These episodes were obviously clearly dictated by the delusional trends, yet the emotions must have remained flexible or else they would not have been capable of responding to demands of the false conceptions. Our patient speaks quite freely of his persecutions, perhaps a trifle too eagerly, and there is lacking the inner psychic tension and self sufficiency which is so characteristic of the paranoiac. Again, he is quite willing to remain in the hospital as a voluntary patient. These two factors may be some indication of beginning deterioration, perhaps of will weakening, but they are certainly not typical or even suggestive of dementia in the præcox sense. There is in schizophrenia a certain asymmetry in the decline of the mental functions. In those paranoid types in which the delusions are fairly well worked out, and in which the intellectual functions are sufficiently preserved to knit them together into a system and maintain them for a long time without shrinkage, we usually find a disproportionate blunting of the emotions. At most, such a patient may rise to a climax of his persecutions by an outburst of anger or a paroxysm of fear, but the reaction to the every day incidents of life is marked by an inadequacy which tells only too plainly of affect blunting. The patient under consideration still retains, after eighteen years, enough emotional pliability to respond adequately to the many situations which commonly arise, even with limited social intercourse. He is quiet, friendly, approachable, and at times mildly exhilarated. He is occupied and, without urging, does a fairly large amount of work in an efficient manner. His muscular movements are natural and well coordinated, and there is no evidence of that awkwardness and stiffness in action and demeanor which frequently characterize defective will inhibition. Attention, memory, and orientation are not affected and there is a fair degree of knowledge of current events.

THE AFFECT.

One of the most serious obstacles which stand in the way of finally pronouncing judgment as to the real position of paraphrenia, is the necessity of attempting to exclude dementia in general, and deterioration of affect life in particular, from the clinical picture. The term, dementia, has been given an unfortunate latitude in psychiatry and has been freely applied to widely varying and even opposed conditions. It has been used to designate the permanent and general mental decline, characteristic of diseases which are directly traceable to demonstrable pathology of brain tissue, as, for instance, paresis; it has been considered the hall mark of dementia præcox, a psychosis for which no anatomical lesion has as yet been established, and in which the deterioration is frequently one sided and may for a long time be purely a matter of conjecture; and, finally, it has been qualified by the adjective "curable" and made to describe the stuporous confusion which is typical of infective exhaustive states. It would perhaps be less perplexing to restrict its application to "those defective mental states in which restitution is impossible." (12.)

Judgment as to affect loss must often be relative. In any unselected group of dementia præcox cases of not too long duration, it is frequently possible to strike practically as many notes on the emotional

*Read at the meeting of the Philadelphia Psychiatric Society, College of Physicians and Surgeons, Philadelphia, Pa., May 12, 1916. The author is indebted to Dr. Earl D. Bond for his assistance in the preparation of this paper.

scale as there are individual patients to be considered. The distance in this respect, between those rapidly deteriorating hebephrenic forms in which at times all the mental faculties seem literally to be swept away by the overwhelming attack of the disease and the slowly progressive delusional types, is immeasurably greater than between the latter and paraphrenia.

The intellect is more easily probed than any of the other mental faculties, and yet we all realize how insufficient and unsatisfactory are the instruments with which we must make our measurements. When we come to gauge the affect we not only have to deal with a far more complex and much less understood property of the mind, but the methods at our disposal are even more limited and less accurate. Of course, complete apathy is self evident, but there are almost infinite gradations between this state and the hypothetical normal affect. In most of the cases of paraphrenia there is some indication of a partial emotional loss. We are particularly likely to find early in the psychosis an unmotived variation between elevated, excited, and depressed states, or at times brief periods of apathy. These are the straws which show which way the wind blows. Might we not explain the relative integrity of affect life on the basis of some intrinsically determined quality of the emotions, which, while it may not be powerful enough to render them wholly impervious to damaging influences, is yet sufficient to turn the main stream of psychosis into other less resistant channels?

WILL.

If we attempt to solve the problem of paraphrenia by an evaluation of will function, we shall find ourselves beset by greater difficulties. Nor can we hope for much enlightenment from the sister science of psychiatry, namely, psychology. American psychologists are devoting most of their attention to the purely experimental side. Unfortunately, the emotional field is difficult of approach by this avenue, while the will is practically inaccessible. In England and Germany there are two bitterly opposed schools of psychological thought. The disciples of so called "association psychology" view our entire psychic life as a reciprocal relation between sensation and conception, and practically deny the existence of independent will functioning; the opposing school, of which Wundt is the most prominent exponent, would endow the will with important and far reaching powers. They regard it as that mental faculty which not only "gives impetus to thought associations, but which also stimulates its servant, the intellect, to produce ideas, to elaborate them by recalling the similar and the incidental, and to recognize causation and effect." (13.) There is much of interest in the discussion, but very slim hope of any practical result which might have an application to psychiatry.

As in the estimate of affect life we find manifestations of such ephemeral and mild nature that we must remain in doubt whether to regard them as pathological or not; so in consideration of will we likewise uncover passing symptoms of such a slight degree that it is practically impossible to decide whether we ought to view them as abnormal or ignore them altogether. Catatonic stupor and negativism are such outspoken indications of defective will inhibition that they occasion us but little difficulty, but the appearance of such incidents as circumstantiality, slight peculiarity of speech or movement, and occasional refusal of food are much harder to interpret. Practically all paraphrenia cases are open to suspicion in this respect. One of the patients I have described was once surprised in the act of going through a series of motions, apparently senseless and purposeless in character.

Attention (14) has been called to the possibility of certain of these so called symptoms being after all merely the end result of a series of conceptions, which, though in themselves abnormal, are yet logical in their connectivity. We can only obtain occasional brief glances into the inner psychotic processes of our patients' lives, and these are certainly not sufficient to permit us to follow with any accuracy the individual steps of abnormal reasoning. If we attempt to reconstruct the chain of thought which finally finds expression in some unusual act, we shall always discover that many and perhaps the most vital links are missing. At best, we may resort to crude theory in order to supply the deficiencies.

It may not be constructive to emphasize the objections which should be overcome before even the relative integrity of the affect and the will in paraphrenia may be granted, yet it seems to be a part of the problem which it would be unfair to ignore.

RELATIONSHIP OF PARAPHRENIA TO MANIC DEPRESSIVE INSANITY.

The resemblance of a number of paraphrenics to victims of manic depressive insanity seems to extend deeper than a mere surface similarity. Kraepelin (15) for a long time regarded all the expansive cases as expressions of the manic phase of this disease. Some of Krambach's patients, especially early in the history of psychosis, showed definite emotional disturbances, such as periods of depression culminating in suicidal attempts or characteristic excitements which were separated by a considerable span of time from the later paranoid condition. Seelert (16) records a well defined emotional cycle with recovery in a patient whose psychosis consisted almost entirely of closely systematized paranoid delusions. In an admission period covering twenty-nine years at the Danvers State Hospital (17), there were only fifty-one cases which were originally regarded as paranoia, and of these thirty-five were later shown to have been mistakenly diagnosed. McDonald, who made a retrospective analysis of the errors, brought out the fact that some of these patients were manic depressives who subsequently recovered. In one of the cases of paraphrenia reported in this paper, there is persistence of a good natured, friendly, and at times elevated emotional tone. I have made a preliminary study of a small group of manic depressive patients all beyond the age of forty-two years, in whom the paranoid trends are most prominent and frequently seem to outweigh the emotional symptoms. In some of them there is evidence of intellectual blunting not unlike that seen in paraphrenia; arteriosclerotic

changes, however, probably play some part in this connection. It is possible that at least a few of the paraphrenias and more particularly of the expansive form may be due to the implantation of a paranoid psychosis on manic depressive soil, which may materially modify its clinical expression. A more remote possibility is the existence of a background of constitutional psychopathic abnormality distorting the picture of an emotional psychosis. Of course, we cannot hope to get much beyond the stage of vague speculation as long as our knowledge of causation remains in its present unsatisfactory state, yet reasoning backward from an unusual symptom complex will frequently suggest strongly an admixture of two disease processes. These are the cases we usually ally to the classification they happen to resemble more closely. In clinical medicine it is not at all unusual to have the symptoms of a disease masked by preexisting congenital, chronic, or even acute pathological processes.

THE INFLUENCE OF THE AGE OF ONSET AND OTHER FACTORS.

The onset in paraphrenia falls so uniformly within the involutional period that it deserves some consideration, not only from the etiological standpoint, but also as a possible determinative factor in the character of the symptomatology. A more intense study of age in its developmental relationship to our various mental faculties, and particularly as to its formative influence on the normal affect, may shed considerable light on our problem. It may be of interest to recall that the forms of dementia præcox in which the emotional loss is most rapid and striking are to be looked for at the period of puberty, when the affect is apt to be most unstable, while the varieties of the disease in which there is a more gradual decline commonly come on in more advanced life, when the emotions are less easily swayed. Mental disturbances are, in some sense, comparable to physical diseases, and it is conceivable that there may be a similar inclination to follow the paths of least resistance, attacking with greatest vigor functions which are most easily destroyed. So in senile dementia, the memory, which has already become impaired by the physiological decline of old age, is most prominently affected. It may be that the time of life in which paraphrenia commonly appears is about coincident with the period when the affect has reached its developmental apex, and thus the emotions are better able to withstand the destructive effects of the psychosis.

The age of onset in paraphrenia is probably also an important factor in determining the profuseness and detail of the delusional content. In the normal mind any isolated conception is enriched and expanded by the number of associations it is able to call up, and these in turn are dependent on the sum total of ideas which have been evolved from past experience of life. While this must obviously remain a variable quantity with each individual, yet it seems reasonable to assume that it has a certain, more or less constant physiological curve. For instance, the first three and probably the fourth decade of an individual's life might be represented by an ascending line, at first abrupt, and then more gradual, indicating periods when, for both intrinsic and extrinsic reasons, the store of knowledge gained by experience is most easily and rapidly increased. Probably toward the close of the fourth decade or in the first half of the fifth, there is a slowing up of the process. The curve representing acquired experience is then maintained at a higher or lower level and is less liable to undergo sharp variations. This is due simply to the fact that situations, as they arise, offer fewer possibilities for the acquisition of entirely new conceptions, because at some previous time the same ideas or similar ones have already been made a part of the consciousness. The measure of experience is almost filled, and further mental advancement is more dependent on a rearrangement, revision, elaboration, and more mature judgment of previously acquired notions than it is upon the assimilation of wholly new ones. An idea which appears at or after such a time is capable of the greatest possible development because it has a lifetime of experience to draw upon for its completion. If this is true for the normal mind, it also holds for the abnormal, unless the brain has deteriorated and systematic thought is prevented by dementia. The profusion and elaborate structure of the delusions in paraphrenia may probably be explained by the age factor. In other words, the time of life at which this psychosis appears corresponds not only to the period of greatest emotional stability, but also represents the beginning of the highest point in the intellectual development.

It is a well known fact that racial characteristics and conditions of life may materially modify the expression of a psychosis. For instance, the symptomatology of dementia præcox is apparently far less complex among the primitive than among the cultured races. Kraepelin (18) found that among the Javanese it uniformly presented a very simple type. There was practically always a preliminary period of confused excitement, which rapidly passed into a final silly dementia; catatonic manifestations were infrequent: hallucinations were rare; delusions of the simplest construction and the prodromal depression which we see so frequently were never observed. Such a clinical expression may in a large measure be due to existing conditions of life, yet the influence of a more meagre or of a different type of brain development cannot be entirely excluded. If the racial factor and all it implies can so greatly change the clinical expression of a disease, it is entirely possible that more delicate variations might be conditioned by independent familial peculiarities of various kinds. On account of the late onset in paraphrenia, it is exceedingly difficult to obtain trustworthy histories, but where the cases can be retraced, there is abundant evidence of distinctly abnormal character traits, many years before the onset of the psychosis.

INFREQUENCY OF PARAPHRENIA.

Paraphrenia is almost as infrequent as paranoia. Kraepelin found only a small proportion among the vast mass of material to which he had access. Eisrath (19) reports nine cases of paraphrenia systematica from a group of 3,520 paranoid patients. Of course, rarity in itself constitutes no real objection

to the entity of a disease, yet when the other factors are so indeterminate, it must incline us to suspect that after all we may be dealing only with an aberrant form of some known condition.

The final decision as to paraphrenia must be postponed until further advances have been made along etiological lines. The studies of Abderhalden have opened a new field which promises to be fruitful. On the side of gross pathology, the work of Southard (20) is at least suggestive. All but two of his series of twenty-five dementia præcox brains yielded distinct evidence of structural abnormality. The chief correlations were between delusions and frontal lobe disease; catatonia and parietal lobe disease; auditory hallucinations and temporal lobe disease. It is interesting to note that the two normal looking brains were those of acute cases and microscopically showed abundant evidence of cell destruction and satellitosis. Whether or not the "brain spot" theory is to survive can only be determined by intensive studies on a large number of brains and a careful checking of the results by histological methods. Should "mental localization," as it might be termed, be advanced beyond the hypothetical stage, the conception of dementia præcox would be vastly simplified, and symptomatic differences would be explainable on the basis of variations in the locus of the gross and microscopical abnormalities. Paraphrenia, too, might eventually come within the scope of such an anatomoclinical correlation.

CONCLUSIONS.

From this rather incomplete study of paraphrenia the following factors stand out most prominently on the side of the "disease process" theory of Kraepelin. The late onset of the psychosis, the fairly close coordination between the delusional content and the reactions of the patient, the absence of definite dementia particularly as regards the affect life, the relative freedom from disturbances of the will, and, finally, the retention of personality.

On the other hand, paraphrenia bears at least a general symptomatic resemblance to dementia præcox; in many cases the emotional field and the will are involved, even though it be only in a minor degree: the presence of a certain amount of deterioration, though this is more inclined to affect the intellectual functions and may in part be due to retrogressive physical changes, especially of the vascular system.

The factors which seem operative in giving an unusual coloring to the clinical picture are the late age of onset with its little understood, but probably significant influence on the development of the affect and will; the possibility at least in some proportion of the cases of a manic depressive predisposition, and, finally, the modifying effect of an inherited psychopathic constitution.

Although at the present time the weight of evidence seems to be against the "disease process" theory of paraphrenia, it is important not to minimize the value of Kraepelin's recent contribution to psychiatry. The exact observational data which he has carefully gathered and emphasized by a special designation, will be extremely useful, even though the conclusions he has drawn are generally regarded as being not entirely justified by the premises. To retain the name, paraphrenia, would not only be a fitting tribute to Kraepelin's work on this subject, but would fill a long felt want in the classification of mental diseases.

CHRONIC SUPPURATIVE OTITIS MEDIA.*

A Modified Radical Operation, Based on Thirteen Cases.

By Hugh B. Blackwell, M. D.,
New York.

Senior Assistant Attending Otolaryngologist, New York Eye and Ear Infirmary; Instructor in Clinical Otology, Columbia University.

In performing this particular operation in the following thirteen cases, my purpose was, 1, to stop the middle ear discharge; and, 2, to conserve, or, if possible, to improve the hearing. All operations were performed in the services of Dr. Robert Lewis at the New York Eye and Ear Infirmary, and Dr. A. B. Duel at the Manhattan Eye, Ear, and Throat Hospital.

OPERATION.

The usual postaural incision is made, as in the Stacke operation. The soft parts anterior to this incision are elevated and retracted forward; the cortex is removed with a gouge and the subcortical cells with curettes until the antrum is opened; the posterior bony canal wall is lowered and the antrum widened to its fullest possible extent. When the short process of the incus becomes visible, the external attic wall is removed by placing the back of the curette external to and in front of the incus and curetting from within outward. The bony canal wall is still further lowered until the facial ridge is reached, leaving only an epitympanic ring in its superior portion, with a width of about one sixteenth of an inch. In four instances I have removed this ring in the superior and outer quadrant of the circle, leaving the membrana tympani and ossicles intact

The granulations, polypi, and cholesteatoma lying in the external and internal attic are removed by

*Read before the American Otological Society, May 9, 1916, Washington, D. C.

curetting internal or external to the incudal body, care being observed not to destroy the suspensory ligament of the malleus or its external lateral ligament. In curetting near the incus, great care must be taken not to disturb the ligament which binds the extremity of its short process to the bone below and just in front of the external semicircular canal. The drum and ossicles are of course not removed, but left *in situ*.

An L shaped metal flap is cut, as in a radical operation, the cartilage removed, and the flap sutured to the temporal fascia. The mastoid wound and attic region are packed snugly, thereby furnishing support to the flap, and the posterior wound is sutured.

Case I. A subacute condition; history of seven weeks' discharge. Operation three years and four months ago; large perisinus abscess, with perforation of the premastoid lamina and necrosis of the adjacent posterior bony wall. The ear has been dry since shortly after the operation. The incus was removed. At present, the patient hears an acoumeter at six feet and a moderate whisper at six feet.

Case II. Ear had been discharging for two years. Operation was performed two years and nine months ago. Cholesteatoma was found in the antrum. Ear remained continuously dry since shortly after the operation. Whisper heard at eighteen inches, and watch only on contact, before the operation. The patient now hears an acoumeter at one foot and a whisper at four feet.

Case III. Ear had been discharging for two years. Operation was performed two years and three months ago. The ear remained continuously dry since shortly after the operation. Prior to the operation, the patient heard a whisper at twenty feet. She now hears a whisper at four feet and an acoumeter at the same distance.

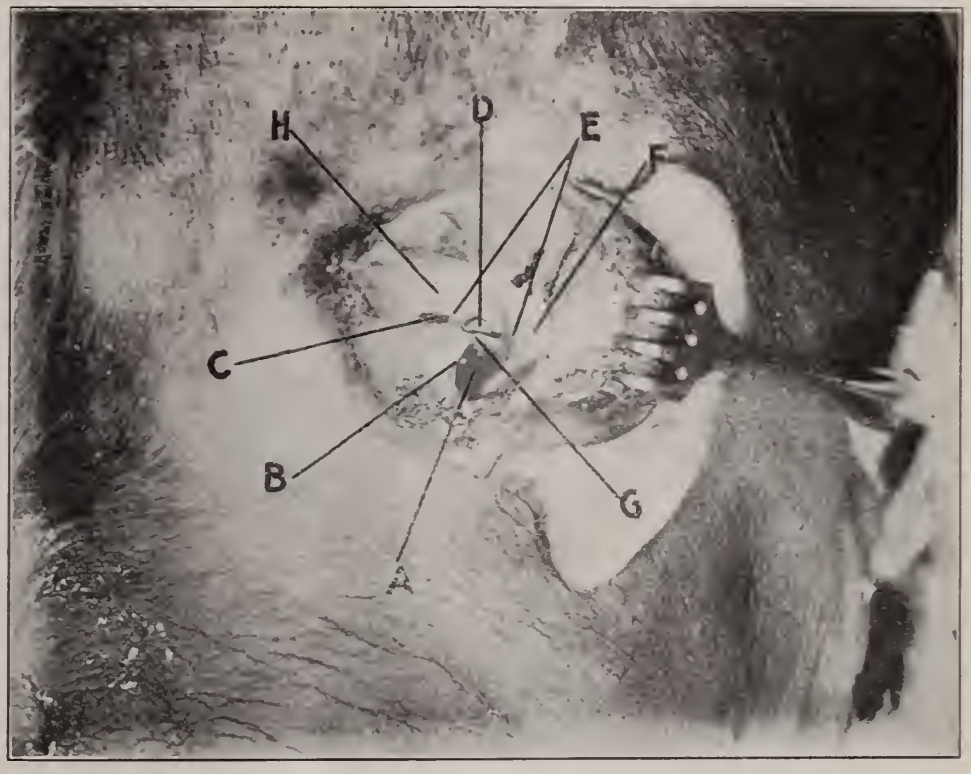

Fig. 1.—View of completed operation, with epitympanic ring intact, taken from behind, prior to closing posterior wound. Drum and ossicles are left intact. A, membrana tympana; B, facial ridge; C, external semi-circular canal; D, malleo-incudal body; E, attic of the middle ear; F, plastic metal flap sutured to fascia of temporal muscle; G, epitympanic ring; H, antrum.

Case IV. Double otitis media purulenta chronica: right ear had been discharging for one and a half year, and the left for six months. Double operation performed two years and four months ago. Both ears are dry and have been so continuously since shortly after the operation. Hearing before operation: Right ear, acoumeter at three inches and whisper at three inches. Hearing now: Acoumeter at two feet and whisper at eighteen feet. Left ear before operation: Acoumeter at twelve inches and whisper at one foot. Hearing now: Acoumeter at six inches and whisper at twenty feet.

Case V. Ear had been discharging for four months prior to operation, which was performed twenty-one months ago. A very large exostosis was present, springing from the posterior wall. Since operation the ear has discharged intermittently. At present there is a very slight discharge from the tube, which is not perceptible to the patient. At present the patient perceives a whisper at five feet and an acoumeter at four feet.

Case VI. Double otitis media purulenta chronica; the right ear had been discharging for six months and the left for two years. Double operation was performed simultaneously seventeen months ago. Both ears have been continuously dry ever since shortly afterward. Hearing at present: Right ear, acoumeter at twenty feet and whisper at twenty feet. Left ear, acoumeter at fifteen feet and whisper at fifteen feet.

Case VII. Clinical diagnosis of tuberculous otitis. The ear had been discharging for five months previous to operation. This was performed one year and four months ago. The ear is now dry, and has been so continuously, with the exception of a slight discharge which began three months ago and lasted for about three weeks. A perisinus abscess was found in this case and the sinus was accidentally opened during the operation. An acoumeter is now heard at two feet and a whisper at eight feet.

Case VIII. Double otitis media purulenta chronica. Both ears had been running for eighteen years, following scarlet fever and diphtheria. Operation was performed a year ago. The left ear has been continuously dry since shortly after the operation. The right ear has been dry at times, but is discharging at present. Hearing prior to operation: Acoumeter, right ear, three feet; left ear, six feet; whisper in both ears at six feet. Patient now hears: Acoumeter, right ear, eight feet; left ear, two feet; whisper in both ears at eight feet.

Case IX. There had been a discharging ear for the past seventeen years. Operation was performed nine months ago. The ear has been dry at times, but is at present wet. The discharge is from the tube. Hearing before operation: Left ear, acoumeter at two feet and whisper at six feet. The hearing since the operation is the same.

Case X. The ear had been discharging for ten years. Operation was performed eight months ago. Since then there has been a continuous slight nonodorous discharge from the tube. Before operation, an acoumeter could be heard at ten feet and a low whisper at ten feet. At present an acoumeter is heard at five feet and a loud whisper at five feet.

Case XI. Patient had a discharge for five years prior to admission to the hospital. Operation eight months ago. (A previous operation had been performed a year before that and the posterior wound had never healed.) Choleste-

atoma was found in the antrum. The ear is now wet. Before the operation the patient heard the acoumeter at ten feet and a whisper at ten feet. Since the operation patient hears the acoumeter at six feet and a whisper at four feet.

Case XII. Patient's ear had been discharging for fifteen years previous to admission to the hospital, following measles. Operation, seven months ago. The ear was dry until three months ago; since then there has been a slight discharge. Hearing before operation: Acoumeter at three feet, whisper at six feet. Hearing now: Acoumeter at seven feet, whisper at ten feet.

Case XIII. Patient had discharge from the ear for five weeks previous to admission to hospital. Operation was performed six months ago, and showed necrosis of the posterior bony canal wall and perforation of the premastoid lamina. The ear is now dry and has been so for over four months. Hearing before operation: Acoumeter at twenty feet and whisper at twenty feet. At present it is the same.

SUMMARY.

These thirteen cases represent sixteen primary operations, for in three instances both ears were involved and a double operation was performed. From the standpoint of duration of discharge, the cases have been arbitrarily divided into two groups.

Fig. 2.—View of completed operation, where the epitympanic ring of bone has been removed in the superior quadrant. Drum and ossicles are left intact. A, membrana tympani; C, external semi-circular canal, D, malleo-incudal body; G, epitympanic ring of bone has been removed between termination of lines; H, antrum.

1. Those in which the discharge had lasted for five years or more, previous to operation;

2. Those in which the ear had been discharging for less than five years.

In the first group, there were six primary operations with the following results: Four of the ears are now wet, and have been more or less so continuously since the operation. The discharge is non-odorous, however, and is much less than before the operation. Two ears are intermittently wet and dry.

The hearing results in the six cases show that in three instances the hearing for the whisper was improved; in one it remained the same, and in two there was a slight depreciation in whisper perception.

In the second group of cases, or those having had a discharge for less than five years, excluding the two subacute cases, there were eight ears coming under this classification. Six of these have remained continuously dry since operation; and two intermittently so. Three of these ears show improvement in hearing, as compared with tests made before the operation.

In the grand total of sixteen operations performed, eight resulted in dry ears, which have been continuously dry since convalescence from operation: four have discharged intermittently since operation: and four continuously. One of the intermittent cases is at present dry.

The longest duration of dryness since operation, in the eleven chronic cases reported, has been two years and eight months: and the shortest has been six months.

With one exception, all the patients were adults. Two cases were complicated by the presence of well marked perisinus abscess. Six had marked constitutional symptoms, such as severe headache, dizziness prior to the operation, etc., and since the operation these symptoms have been relieved. In two instances, cholesteatoma was found in the mastoid; one of these cases resulted in a dry ear, which has remained dry for over two years. In none of the thirteen cases did the patients think the hearing had become impaired since the operation. It is interesting to note that in Case XIII, the hearing was almost normal before the operation; it is the same at present, showing that, in this case at least, the procedure had no ill effect upon the hearing.

All the cases ended in recovery. In the nine healed and dry ears, it is interesting to observe the amount of repair which has taken place in the tympanic membrane. Six of these cases now show intact drums, despite the large perforations which formerly existed. In three of the cases, half of the drum membrane was missing. The remaining five cases show large, dry, unhealed perforations.

An interesting feature is the development of a secondary tympanic membrane, which is all but one of these cases has grown across the attic region in the process of healing, completely closing off the attic from the mastoid cavity.

In applying the dressing, it is necessary to pack the attic region snugly until it becomes well dermatized; otherwise it will soon become filled with a thick plug of granulations which, if infected, will be apt to discharge copiously, reinfect the middle ear, and prevent its proper aeration. It is probable that the discharge which occurred in two of the wet cases in this series was caused by the failure properly to appreciate the importance of this point.

It will be seen that the best results were obtained in the second group of cases, namely, those having a history of discharge lasting less than five years. The procedure seems especially applicable in this class of cases, and more particularly in chronic cases in which there is good hearing.

I believe that this operation is indicated in cases of aural discharge of several months' standing, which have resisted treatment, and where the patient is threatened with the possibility of long continued suppuration. I do not think that the presence of a large perforation, or the absence of half the tympanic membrane is a contraindication to the operation, as demonstrated by some of these cases.

The important element to be considered in cases of subacute and chronic otitis media, in the absence of constitutional symptoms, is, of course, the hearing. If this is good, and the discharge is of less than five years' duration, I believe this operation to be especially indicated. In cases of exostosis of the canal associated with otitis media purulenta chronica, and in perforation of the premastoid lamina associated with necrosis of the posterior bony canal wall, it should be the operation of choice. Another point in favor of this procedure is that the danger of causing an injury to the facial nerve is negligible.

CONCLUSION.

This operation is not presented as one that would entirely replace the radical procedure; the latter has its own distinct field of usefulness. It is very difficult to compare the results obtained from a radical operation with those obtained from a modified radical operation, save in a general way, since of course no one can say what the results would have been in any one of these cases had a radical operation been performed. I am convinced, however, that the functional results compare favorably with the best which follow the radical operation; and that in the future, as we learn better how to select cases for this modified radical operation, it will yield even better functional results as well as a dry ear.

148 WEST FIFTY-EIGHTH STREET.

Painless and Shockless Childbirth.—M. W. Kapp (*Medical Record*, August 5, 1916) reports the use of his own method of obstetric analgesia without amnesia. It consists in the hypodermic administration of heroine hydrochloride in doses up to one half grain to produce the required insensitiveness to pain. If the pains are retarded by the heroine, then pituitrin may be employed to rearouse uterine contractions. By this method shock is lessened, labor is shortened; valvular cardiac trouble and albuminuria are not contraindications.

ORTHOPEDICS OF THE HAND.

A Report of Two Cases.

BY LAWRENCE G. HANLEY, M. D., LL. D.,
Buffalo, N. Y.

My first case is one of grafting of the terminal and middle phalanges and restoring the ungual phalanx of the index finger. I was called to attend Frank Smith, aged seven years, August 1, 1892. His index finger of left hand had been cut off in a hay cutter at the junction of the middle and terminal phalanges. I saw him about one hour after the accident. The severed portion of the finger was in a cloth on the table. An anesthetic was given and the amputated part was sewn on with silk sutures. The hand was put into a water bath, saline solution, and kept there for two weeks. The middle phalanx

FIG. 1.—Index finger was cut off twenty-four years ago, was replaced under saline solution and healed completely. A shows line of union.

was cut diagonally, but the joint of first and middle phalanges was not injured.

The parts united and flexion and extension are perfect, but he suffers slightly from cold in the tip of the finger. Fig. 1 shows the difference in size. There was no pressure from bandages and dressings to interfere with the restoration of circulation, and the heat from the water also aided. This was done twenty-four years ago, and the photograph was taken April 1, 1916.

My second interesting case was that of Loretta McGee, a clerk aged twenty-seven years, who, on November 27, 1914, while dusting under a coffee machine, had part of the ungual phalanx of the index finger cut off at the junction of skin and nail. She was seen by me one hour and a half after the injury, minus the top of the finger.

I applied adhesive strips lengthwise to the finger, from the middle of the hand to the tip, attempting in a manner to draw skin over the top. The dress-

ing was left on for one week with a blood clot on the cut surface. Subsequent dressings were applied in the same way as already described. It took nearly four months to grow the nail and produce

Fig. 2.—Tip of left index finger was severed two years ago; it was replaced under a blood clot, and functions perfectly.

the conditions shown in Fig. 2. The nail is perfect, but the finger is a trifle shorter and thinner than normal. I have succeeded in several cases in shaping and preserving the ungual phalanges by this method.

428 Porter Avenue.

FROST BITE IN THE HAND RESEMBLING RAYNAUD'S DISEASE.*

By N. S. Yawger, M. D.,
Philadelphia.
(From the Department of Neurology, University of Pennsylvania.)

Case. The patient, aged thirty-one years, a brakeman on a passenger train, was referred to the surgical dispensary of the University Hospital, with a condition in the right hand which it was feared might necessitate amputation. The patient was transferred to the nervous disease service. Family history: Nothing was revealed suggestive of vasomotor disorders. Personal history: Habits were good; he did not drink and denied ever having had a social disease. He was the father of one healthy child; his wife had since had a miscarriage at about three and a half months. There had been practically nothing to indicate an unstable vasomotor system—no hemorrhage from any part of the body, no vertigo nor impaired vision; no "dead" fingers or toes; nor had he had chilblains on his hands, feet, or ears. Upon two or three occasions there had been slight urticarial manifestations after eating certain articles. There had never been disability or disturbance in the arm previous to the exposure.

History of accident: In December, 1912, while at work as a brakeman, the patient had his right hand frozen. The temperature was about 10° above zero and the exposure was for a half hour, at the end of which time a glove that he had been wearing and which was perfectly dry, was removed and the hand was found to be seriously swollen. The edema subsided as soon as the part was warmed. For two months there was absolutely no trouble and then, without known cause, the finger tips felt cold, sensitive, and painful. The pain, which soon became intense, was stinging in character; it extended up the fingers and through the hand as far as the wrist. There was no swelling nor was there sufficient disability to prevent the patient performing his duties satisfactorily. The pain was almost constant for six months, though the intensity varied. Then followed a period of a little more than two years with freedom from all symptoms.

In October last, the patient was obliged to have his hands in cracked ice for about fifteen minutes, and twenty-four hours later severe symptoms developed in the right hand. At first the part felt numb and then the wrist became swollen and painful. This was followed by the development of ulcers; there were eleven of these, mostly along the ulnar edge of the hand and at the tips of the fingers. The thumb and all fingers were affected, except the little finger. Some of the ulcers lasted for two months; in fact, one of the sites has to be protected at the present time. The growth of the finger nails was markedly retarded for some weeks. The patient was told that he had Raynaud's disease and that he might lose his hand at any time.

The patient's general appearance was good. The heart action was normal and there was no evidence of nervous disease or disorder of the vascular system other than the condition of the right forearm and hand. The coagulation time of the blood was studied by Dr. George Dorrance, who reported it normal. The Wassermann test in the blood was negative.

There is at present no appreciable loss of power, and the hand is used steadily at work, but every precaution is taken to prevent exposure to cold. No discomfort is experienced, except for a slight chilly feeling and this is always present. The circulation in the hand is easily affected, for instance, elevation usually causes prompt blanching.

Examination of the affected part shows two depressed cicatrices at the ends of the thumb and index finger. There is a well marked transverse groove across the nail of the ring finger. To the examiner the temperature of the affected hand feels slightly lower than that of the opposite side. There are no changes in pain, touch, and temperature sensations. Attempts to get the radial pulse usually fail, though occasionally a very feeble movement is detected. The ulnar pulse is distinctly more feeble than that of the opposite side. There is no appreciable difference in the pulsation of the arteries at the elbows, and the blood pressure in the two brachial arteries is equal, 130 mm.

The case is unusual and I have not been able to find the record of a similar one. Déjerine and Muzon (1) have reported a case where pressure from a cervical rib upon the subclavian artery led to ischemia of the extremity and subsequently to thrombosis. Their patient had experienced pain and numbness in the hand for some time; then the fingers became white and tender, severe attacks of itching developed, and there were urticarial manifestations; the part was threatened with gangrene, and a resection of the rib was done at which operation the thrombosis was discovered.

Our patient has a slight enlargement above the right clavicle and this led to a röntgenographic study of the cervical region. There was reported to be an incomplete cervical rib in the right and a rudimentary one in the left. It was not thought that the rib was sufficiently long to exert pressure, nor do the clinical findings point to such a condition.

*Read before the Philadelphia Neurological Society, March 24, 1916.

As to Raynaud's disease, this disorder need not affect corresponding areas, as is stated by Cassirer (2), "for example, I saw a case of this kind in which there appeared to be a congenitally weaker arterial vascular system of the affected arm." In our patient we know of no disturbance in the part previous to exposure.

A feature of present day military tactics is trench warfare, and this has brought out the baneful effects of cold on the feet. Abroad, much has been written recently upon the subject of disturbances that follow soon after exposure, but sufficient time has not yet elapsed to acquaint us with the more remote effects. It has often been questioned whether in frost bite the damage is greater to the bloodvessels or to the nerves. In order to come to a better understanding of this distressing condition, Smith Ritchie, and Dawson (3) recently made an experimental investigation and their findings are most instructive; they show much more extensive injury to the bloodvessels. These observers subjected rabbits to conditions similar to those of soldiers in cold, wet trenches. Subsequent microscopic study of the bloodvessels showed dilatation, a deposit of fibrin along the lining, swelling of the endothelium, and vacuolization of the muscle fibres of the media; there was also an increase of cells in the perivascular tissue. The nerves showed no degeneration of the myelin and the swelling which was present in the axis cylinders existed, they believed, as a result of the general edema.

The condition in our patient appears to have resulted from frost bite and subsequent exposure to cold. There probably has developed an inflammatory process which has gone on to sclerosis of the bloodvessels, and since no irregularities can be made out, it is assumed that the condition is more or less uniform. The striking vascular disturbance and the absence of nerve changes appear to bear out the findings in the experimental work of the English investigators just cited.

THE VALUE OF IODINE IN GONORRHEA.

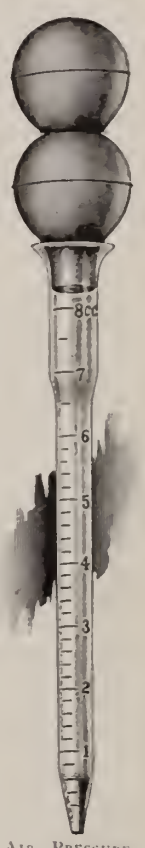
BY M. ABRAMOVITZ, M. D.,

Baltimore.

The net summary of the pathology in gonorrhea and gonorrheal affections in the various stages being: "Bacteria invading tissue, causing at first a round cell infiltration and later connective tissue formation," the idea suggests itself at once, Why not combat it with iodine? Iodine in proper strength will undoubtedly kill bacteria. Iodine favors the absorption of connective tissue and prevents its formation. Iodine will neutralize the action of the agents which prevent the solution and absorption of necrotic tissue, and at the same time uncover and lay bare to the action of a germicide the germs which were protected by the necrotic tissue (1). Iodine has a peculiar attraction for specifically inflamed tissues (2).

Iodine would thus be the most valuable agent to defeat the pathological condition in gonorrhea if not for its violently irritating qualities. In fact, the idea of iodine in gonorrhea has undoubtedly occurred to many as it did to the writer. Bargues (3) tried iodine in urethritis, but found it so irritating that he abandoned it after a disagreeable experience. Iodine for intraurethral injection serves as the proverbial sour grapes to the urologist.

Recently much has been done in the research of colloidal drugs with gratifying results. Colloidal drugs have proved overwhelmingly superior to the crystalline. A very interesting study of colloids by McGuigan (4) bears out the statement that colloids protect the sensory nerves, as shown by the fact that sugar dissolved in mucilage tastes less sweet than in water. For the same reason ice cream does not taste as cold as ice (Cushny). He also shows that the toxicity of crystalline substances is in many cases ninety times greater than that of colloids. The reason is that colloids are absorbed slowly. The absorption of a colloid can be lessened to such an extent that the rate of excretion may be nearly equal to the rate of absorption, in which case no toxic action would or could be expected. Diamond (5) explains why a colloid will act much better than the same drug in the crystalline form; it is because colloids have the property of adsorption, i. e., the property of charcoal to store up large volumes of gas. The minute subdivision of colloid particles effects enormous surface absorption.



AIR PRESSURE SYRINGE.

Pressure on the upper bulb expels the contents of the syringe and moderately inflates the urethra. Continued pressure on the lower bulb without changing the position of the hand will inject in the uretha a fresh volume of air which, by the voluntary relaxation of the compressor urethræ muscles by the act of urination, will drive the drug up into the posterior urethra.

Aware of the prohibitive qualities of crystalline iodine, and the possibilities of the same drug in the colloidal state, the idea of the intraurethral injection of colloidal iodine strongly appealed to me, especially after reading the many favorable reports of well known European clinicians, asserting the full effect of iodine minus the irritation. Such was the report of Auregan (6), which showed that this form of iodine had no irritating effect on open wounds, while it was effective in the reduction of the mortality of tetanus from sixty to 31.2 per cent.

The employment of a French preparation of electrocolloidal iodine for nearly a year in every case of gonorrhea presenting itself for treatment, with an improvement from time to time in the technic, gave net results as described briefly in the following case reports:

GROUP I (hyperacute anterior urethritis), twenty cases; youths and young adults. History of recent infection with

rapid development. The tissues were highly inflamed with more or less swelling. Severe burning on urination. Profuse yellowish green discharge. Microscopic examination of the discharge showed numerous intracellular gonococci with many floating free in the fluid portion of the pus (apparently from the overfilled and ruptured cells).

Technic of treatment. The patient was instructed to urinate. The anterior urethra was flushed out with a warm mild solution of boric acid. The urethra was then stripped by gently milking it toward the meatus for the purpose of having it as dry as possible. Two or three c. c. electrocolloidal iodine was drawn up in the air pressure syringe (see figure), which had been previously sterilized by boiling and made absolutely dry (by either wiping it with sterile cotton on an applicator or by passing absolute alcohol through the barrel of the syringe). The end of the syringe was inserted into the meatus, which was made to fit well around the tip of the syringe, and with pressure on the bulb, the drug was discharged into the anterior urethra, utilizing the air cushion back of the drug to inflate moderately that portion of the urethra and so serve to open the pus pockets in the depressions or sacculations of the canal. The syringe was then withdrawn, while the left hand holding the penis compressed the meatus so that no air or drug escaped. The penis was then raised and lowered several times so as to allow the drug to cover the mucosa of the entire anterior urethra and thus reach every infected area. The enormous surface absorption of the colloid amply covered the mucosa. Absorbent cotton was then applied and fixed over the glans by a rubber band. The patient was instructed to dress the penis for a short time flexed over the symphysis pubis, which allowed the drug to stay in the canal by gravitation and not be discharged on the cotton, as it was when the penis was allowed to hang downward. The treatment was repeated twice daily, with the result that the gonococci disappeared in five to seven days with complete recovery in ten to twelve days.

In none of the foregoing cases was there and extension of the inflammation causing complications, nor was there any connective tissue formation. The latter fact was ascertained by repeated endoscopic examinations after recovery. The absence of complications can be explained to be due to the oily base of the drug which materially helped drainage by keeping the urethral walls apart. Extension of the inflammation was thus arrested.

I have found that the most practical way to keep the syringe sterile for the next injection is to fit to a large test tube a cork with a hole cut therein to admit the barrel of the syringe. The test tube is filled with absolute alcohol, which keeps the tip of syringe submerged.

To patients unable to come to the office more than once daily, I gave an outfit consisting of a flask of the drug, a sterile syringe in a sterile test tube with alcohol as described above, and one practical demonstration was given to the patient at the office, which enabled him to carry out the treatment at home twice daily without difficulty.

I found that in some of the cases, where there was great swelling and pain, that previous irrigation of the canal by a 0.2 to one per cent. sodium chloride solution, made the application of the drug absolutely painless. This proved useful in hypersensitive youths during the first few treatments. The action of sodium chloride—according to Hanzlick (7), when applied to mucous membranes, is to prevent the absorption of iodine.

GROUP II (moderately acute and subacute urethritis), fourteen cases; adults or middle aged men. History of recent infection with rather slow development. Very little or no pain on urination. The discharge was of a mucopurulent character. Gonococci (intracellular) present in the discharge. Six of the patients gave history of this being their second or third infection. Urine examination and endoscopy promptly placed them in the group of chronic cases. The remaining eight were treated as described in the technic of Group I. These cases terminated favorably in from two to three weeks.

GROUP III (chronic posterior urethritis), twelve cases; adults and middle aged men. History of infection, six months to many years. Microscopic examination of the urinary shreds and particularly the so called morning drop showed gonococci plus staphylococci, streptococci, and colon bacilli. Endoscopically, the posterior urethra presented a picture of erosions, ulcerations, and granulations. Slight narrowing—beginning of stricture—was noted in two of the cases.

Technic of treatment. As in most cases in that class, there was an involvement of the prostate, which was massaged two or three times weekly. After the massage the patient urinated. The urethra was irrigated with a mild solution of boric acid, allowing some of the irrigating fluid to enter the bladder at the end of the irrigation. The patient then completely emptied his bladder. The urethra was stripped as described above.

Five or six c. c. electrocolloidal iodine was drawn up into the double bulb syringe; the end was inserted into the meatus, which was held so as to fit around the tip of the syringe. The penis was raised to an angle of about 45°. The upper bulb was pressed, which discharged the contents of the syringe into the anterior urethra. The air cushion back of the drug drove it down the incline to the bulbous urethra or just in front of the membranous urethra, which at this point is larger in calibre. The patient was then instructed to urinate, the effort of which voluntarily relaxed the compressor urethræ muscles, while at the same time pressure was continued on the lower bulb, injecting a fresh volume of air into the urethra, which easily drove the drug into the posterior urethra. The natural curve and the dilated middle portion of the posterior urethra, the ridge (verumontanum), and the depression (sinus pocularis) in its posterior wall in all cases retained the drug, while any excess of air passed over into the bladder to escape at the end of the next urination. The penis was dressed as described above. One such instillation daily proved very effective. Recovery was complete in eight to ten weeks. The air pressure instillation proved to me invaluable. It not only made possible a quick and painless instillation of the drug in the posterior urethra, but it completely does away with instrumentation, which is always more or less traumatic.

GROUP IV (gonorrheal vaginitis and endocervicitis), five cases. History of infection. Microscopic examination of smears taken from vagina, cervical canal, and urethra, showed the infection (gonococci) present in both the vagina and the urethra. The urethra was treated as before. The vagina was cleansed by a warm antiseptic douche and wiped dry with sterile cotton or gauze. A suppository containing twenty-two grains electrocolloidal iodine in a gelatin-glycerin base was inserted into the vagina and fixed just in front of the cervix by a light gauge tampon. The patient was instructed to keep it undisturbed for two or three hours, after which she removed the tampon and irrigated the vagina with warm saline solution. One such treatment daily resulted in complete recovery in ten days to two weeks.

As pain is an important factor to the patient as well as to the physician, I beg to say, in conclusion, that the treatments above described are painless. But it must be remembered that colloids do not keep well because the electrolytes therein precipitate the particles in suspension. Care must be taken to use only such colloidal iodine as has been by proper dialysis freed of electrolytes and made absolutely stable, if the practitioner is desirous of attaining satisfactory results.

Food and Food Preparation, in Health and Disease

DISORDERS OF NUTRITION IN INFANTS.*

By Nicol Martin Mandl, M. D.,
New York,
Attending Pediatrist, Hospital for Deformities and Joint Diseases; Attending Pediatrist, German Policlinic.

The short space at my disposal as well as the immensity of the subject make it impossible to do more than merely emphasize some of the most important phases of the disorders of nutrition in infants. It is advisable to divide this subject into two main divisions:

1. Disorders of nutrition indirectly attributable thereto;

2. Those which may be attributed to faulty nutrition as a direct cause.

Under 1, I shall classify the diseases of the mouth, such as stomatitis, whether of bacterial, chemical, or thermic origin as a primary condition, or secondary to infectious diseases such as scarlet fever, measles, etc. Of all the various forms, stomatitis catarrhalis is the most frequent in the newborn and in infants, and is often complicated with soor and Bednar's aphthæ, which is a decubitus of the palate over the hammulus pterigoideus. Such mechanical erosions result from too vigorous attempts to clean the oral cavity, of which there is no need prior to the eruption of the teeth. A light swabbing of the mouth after the daily bath with sterile water is always sufficient.

Soor is a disease of the suckling age—seldom in older children. It is due to a fungus (Oidium albicans). We know now that it is a harmless nosoparasite and that deadly general diseases are not due to this cause, but that it may form a primary disposition for them. Again I repeat that many an infant has been affected by this disease through much busying in cleansing the oral cavity, thus forming traumatic lesions for the development of soor. I should like to be permitted to make a therapeutic suggestion; sterile gauze dipped in a ten per cent. boroglycerin solution with which the nipples are covered and through which the child then sucks will be found a most effective measure.

The esophagus with its congenital or acquired stenosis and a spastic pylorus are other sources of nutritional diseases in infants. In my student days the generally accepted theory was that of one of my teachers in Vienna, Professor Widerhoffer, who declared that the diseases of the stomach and intestines like dyspepsia, gastroenteritis, etc., are in every way similar to these diseases in adults, with the *single exception* that the greater severity of these diseases in infants is caused by their physiologically lesser resistance. The fallacy of this theory is now recognized. It is interesting to note that even in the cases showing the most severe clinical symptoms the pathological findings show slight lesions. Bacterial invasion is considered a lesser cause of disorder of nutrition in infants than heretofore believed; to the introduction of food are due general metabolic disturbances known as diseases of the digestive system which lead us to the pathology of digestion. Formerly our principal thoughts centered around the decomposition of milk or turned to bacteria originated diseases as a cause of disorders of nutrition. Today we pay much less attention to this cause than to the *quality* and *adaptability* of food for infants. In other words the *tolerance* of the individual child for food is the primary consideration in the feeding question. Too little food and too much food are the principal causes of the disorders of nutrition, and this is a cardinal point.

To the first group belong cases of inanition due to simple hunger feeding, or to qualitatively unsuitable diet, or to the continuation of certain food for too long a time. If the tolerance for food in infants is overstepped, stagnation results and abnormal bacterial decomposition follows with its consequences.

Constipation in breast fed infants is due mostly to lack of nourishment. The food is absorbed in the upper intestines and does not produce any ferment for forming acids, which acids in turn cause peristaltic movements in the large gut. Artificially fed infants suffer from constipation through lack of suitable food, or qualitatively unsuitable food like a continued diet of cereals, rickets (muscular atony), and deficiency of fat in the food. Overloading the stomach with food highly diluted causes dilatation of the stomach and retards digestion, thereby producing stagnation and its resulting evils.

Overfeeding produces a circulus viciosus. The surplus food absorbs the free hydrochloric acid and prevents its stimulating action on intestinal digestion and pancreatic and bile secretion. This again results in stagnation which produces acid fermentation, giving rise to gas and increased peristalsis and causing green, watery, acid, odorous stools.

As a result of too much food we may have a gastritis in an acute form (due to the presence of irritating ingesta or to improper quantity of food or unwisely chosen periods of feeding). Intestinal colic is due to flatulence produced by undigested foods rich in fat and sugar.

In addition to insufficient food and to overfeeding, disturbances of nutrition in infants are further due to insufficiency of the digestive organs. In prematurely born infants there is deficiency of absorption and assimilation and the stomach, of course, has a smaller capacity. In artificially fed infants the cow milk containing more salts neutralizes the free hydrochloric acid. This permits bacterial proliferation and gives rise to the most tormenting symptoms of the infant's life—colica flatulenta.

The question most often confronting the pediatrist is that of the doubtful result produced in feeding with cow milk despite its (close) similarity to human milk. The question has aroused much discussion and given rise to various theories. We were taught by Biedert that the casein of the cow milk

*Read before the Yorkville Medical Society, May 15, 1916.

was hard to digest. Hamburger attributed the trouble to the difference in the albumins; Pfaundler and Escherich assert that special ferments in the human milk act as stimulants to digestion. Epstein avers the difference to be due to the fat, Cerny to the fat and sugar content. These are the most frequent causes of fermentation and irregularities in the digestion through the formation of acids, lactic and butyric, and are of main interest.

So much has been written and said on the subject of infant feeding that I shall permit myself only a few suggestions.

Infants of the same age require to be fed according to weight and size; starch should be added from the seventh month on; irregularity in feeding must be avoided: malnutrition is the first stage of marasmus.

And in conclusion may I add a few clinical remarks? Fifty per cent. of all cases of intussusception are found in infants and are due to very lively peristalsis. (The great frequency of intussusception in boys is due to the reflex irritation of an adherent prepuce). Intestinal parasites are often the cause of intestinal obstruction. *In the bottle fed*, hyperthermia is one of the primary causes of summer diarrhea.

Mercury salicylates, and codeine are excreted in breast milk and should therefore be avoided in medication of the nursing mother. The milk of the tuberculous or nephritic woman may injure the infant.

Cow milk *should not even be tried* in the first week of life. The so called milk injuries of Czerny and Keller are due to the high fat content.

Overfeeding causes stagnation of the gastric contents.

Starchy foods in early life are the cause of severe diseases of nutrition. Early feeding of eggs produces severe disturbances, skin eruptions, and nervous phenomena.

As a final dogma—breast feeding is superior to any other and the physician should *insist* on its practice wherever possible.

1097 Madison Avenue.

CARING FOR MILK IN THE HOME.

The three C's for the proper care of milk in the home are:

Keep milk { Clean; Cold; Covered.

The practitioner should draw the attention of his patients to the fact that milk is a highly perishable food, and the length of time it will remain sweet and safe, especially for children, depends almost entirely upon the constant care it receives between cow and consumer. Milk passes through three agencies—the producer, the dealer, and the consumer. If the first two have done their part, clean, safe milk will be delivered, thoroughly chilled, to the consumer. The consumer's responsibility begins the moment the milk is delivered at his doorstep.

Tell mothers who do not nurse their babies that because milk poured from vessel to vessel on the street is very liable to contamination from dust, manure particles, and germs, it is best delivered in capped bottles. If bottled milk cannot be obtained, the housewife should try to have some one in the family receive the milk in a clean, scalded utensil, cover it instantly, and put it without delay into the refrigerator, or the coldest available place. Under no circumstance should an uncovered pitcher, bowl, or pan be left out on the porch to receive bulk milk. The vessel, both before and after the milk is poured into it, is accessible to flies and collects particles of dust and dirt.

Even in the case of bottled milk, however, the consumer must see that the bottle is not left out in the heat for a moment longer than is necessary. Milk should be delivered and kept at a temperature of 50° F. or lower—the colder the better. At such temperatures bacteria develop very slowly and milk undergoes little change until consumed. A slight rise in temperature above this point, however, permits bacteria to multiply rapidly and brings about rapid deterioration of the milk, which may render it unfit for ordinary use and make it highly dangerous for babies and little children. For this reason bottled or other milk should not be allowed to remain in a warm place, as on a sunny porch or in a hot kitchen, for a moment longer than is necessary.

DELIVERY OF MILK IN HOT WEATHER.

In hot weather the best plan is to have the milkman put the milk directly into the refrigerator, because at that time of year milk cannot be kept properly without ice. If a refrigerator is not available, provide a small box containing ice, and if ice is unobtainable, provide some tight container with insulated walls that keep the heat from getting rapidly to the cold milk. A home made fireless cooker is admirable for this purpose, especially if partially filled with ice. In the absence of any of these devices, arrange with the milkman not to leave the milk in the sunlight, but to put it in the coolest, shadiest place around the house. If the bottle is wrapped in a piece of clean unbleached muslin and stands in cool water, the cloth will be kept wet by capillary attraction, and the evaporation of the water will keep the milk cool.

HANDLING MILK IN THE HOME.

In handling milk around the home, do not pour it from one vessel to another until it is to be consumed. Do not let the bottle of milk remain out of the refrigerator a moment longer than is necessary. Keep the milk covered, using paper caps or an inverted tumbler on bottles, or store it in clean, covered utensils. Any household utensil that is to be used as a vessel for keeping milk should first be cleaned thoroughly and scalded.

Before opening a bottle of milk, wash and wipe the neck and outside of the cap with running water The little depression on the top of the cap may collect dust or water and any milk that leaks out may attract flies. Lift out the cap with a pointed instrument or piece of sharpened wire kept for the purpose, so that the outside of the cap, which may be contaminated, will not be pushed down into the milk. Each time the milk is to be poured from the bottle, it is a wise precaution to wash the neck as described.

MILK IN A REFRIGERATOR.

The refrigerator where milk is stored should be cleaned regularly, especial care being given to keeping the drip pipe free and clean. The ice rack also should be cleaned, and any place where food is kept or milk stored should be scalded occasionally with sal soda solution. The refrigerator, even though cold, may quickly be contaminated by a few drops of spilled milk, or by small particles of food. No matter how clean the refrigerator, milk should never be kept in an open vessel. As milk absorbs odors easily, such food as fish, cabbage, or onions should not be kept near it.

CLEAN EMPTY BOTTLES.

As soon as a milk bottle is emptied, rinse it thoroughly with cold water. Do not return dirty bottles and do not use milk bottles except to hold milk. Returning dirty bottles to the milkman may mean that a few days later either you or your neighbors will get contaminated milk. In towns with proper sanitary regulations, this practice is forbidden by law. Milk bottles should never be taken into a sick room. Where infectious or contagious disease is in the house, all bottles should be boiled thoroughly and should not be returned to the dealer without the express permission of the attending physician. Such diseases easily can be made epidemic through disregard of this precaution.

WHERE THERE ARE CHILDREN.

Care of milk, important for all, is a vital necessity in a home where there are children. It is absolutely essential to the safety of babies. No careful mother will leave to a servant the task of caring for or preparing the milk for her baby. Mothers of small children should get, from their own physicians, explicit directions for the proper handling of milk and for cleaning and sterilizing nursing bottles. Pamphlets on infant feeding may be obtained from the municipal milk stations or health officers. Milk for babies cannot be kept too cold, and too much care cannot be given to keeping it clean and covered.

Further information on this subject may be had by writing to the U. S. Department of Agriculture, Washington, D. C., for Farmers' Bulletin 413, *Care of Milk and Its Use in the Home*.

The Diet of Children after Infancy.—J. H. Mason Knox (*Jour. A. M. A.*, August 5, 1916) notes that an enormous amount of time and study has been devoted to the dietetic requirements of infants, but that relatively little has been spent upon the equally important problem of the diet of children during the following period. From the few available studies the average requirement for a child of two years may be stated as ninety-four calories per kilogram: for one of four as eighty-two, and for one of eight as sixty-seven calories. The actual amount of food increases gradually from infancy to maturity, but the relative amount per kilogram of body weight decreases. There are wide variations from averages stated in individual cases, but the averages serve as valuable guides for most children. Little definite is known as to the required proportions of protein, fat and carbohydrate for children, but if sufficient fat and carbohydrate is supplied relatively little protein is needed. Not more than about four grams of protein per kilogram of body weight is required for children under eight, and about half that amount for those above this age. About half of the protein should be derived from animal foods, but as the child grows older this proportion should be reduced and more should be provided from the vegetable kingdom. About four grams of fat per kilogram seems to be required at the age of two, and half that amount after ten. The minimum fluid intake at two years should be about one liter, increasing to one and one half liters by the age of seven. The vegetables provide a sufficiency of mineral salts and this element needs no special consideration. Bearing these estimates in mind, the physician should construct a series of diets suitable for children of different ages which would provide the necessary amounts of the several food constituents in a balanced diet. The additions from the period of infancy should begin with the simplest forms of food and the diet should be made increasingly more complex as the child's age advances. Special attention should be paid to the modes of preparation of the several foods ordered, and it is the duty of the physician to be able to give explicit directions on this phase of the problem. The author gives several suggestive diet lists for different ages, but these may be modified very largely to suit individual conditions. It should be borne in mind that the young child does not require any great variety in his diet and it is sufficient to have a few alternatives which can be used on different days.

Recent Progress in Dietetics as a Science.—R. de W. Baker (*American Journal of Electrotherapeutics and Radiology*, June, 1916) calls attention to the marked practical significance of the newer conceptions relative to the proteins and their decomposition products. Proteins are to be considered important, not from the standpoint of their content of carbon, nitrogen, hydrogen, etc., but from that of their yield of the desirable aminoacids, eighteen in number, used by the organism for tissue construction and repair, e. g., tyrosin, leucin, tryptophan, lysin, glycocoll, cystin, histidin, arginin, etc. Specific functions have been shown by Mendel and Osborne to belong to certain of these aminoacids, only a certain number of which are needed for the maintenance of nutrition in the adult, though nearly all are required for tissue construction or repair. Thus, the nutrition of adult animals is maintained by the gliadin of wheat given as the sole protein, but growing animals cease to gain unless lysin is added. Zein, the chief protein of the maize kernel, which yields no lysin, tryptophan, or glycocoll, does not alone meet the nitrogenous needs of animals, but when supplemented with tryptophan, maintains body nutrition, and with lysin in addition, body growth. The individual aminoacids can be manufactured, and some made by the body itself when required. Bacteria, acting on excess of protein or aminoacids in the alimentary tract, or protein in lumps, form toxic substances. Cadaverin, for example, is formed from lysin; indol and skatol, from tryptophan; and phenol and cresol, from tyrosin. Interesting possibilities arise in influencing the reaction of the body juices by the use of base forming foods such as po-

tato, and acid forming foods, such as meats. The unknown but essential food substances called vitamines have also recently excited much interest. Animals failing to grow because of feeding upon lard, which contains none of these substances, begin to gain as soon as milk fat, egg fat, or codliver fat, which does contain them, is added to the diet. The entire subject of protein diet and nutrition is thus being transferred from guesswork and assumption to a scientific basis.

The Nutritional Value of Bread from the Whole Grain.—F. Röhmann (*Berlin. klin. Woch.*, January 31, 1916) states that much of the protein of the grain is contained in the layer immediately beneath the pericarp and is not utilized when eaten as ordinarily milled for whole grain bread. Aleuron cells can often be found whole in the human stools after the use of such bread. When, however, the grain is very finely ground so as to pulverize this hard outer layer a much larger proportion of its proteid contents is made available. Bread made of such finely milled whole grain has a much higher nutritive value than ordinary bread and provides so much additional protein that it very largely spares the much more expensive protein foods, such as meat. In addition to this the outer layer has been found to contain certain substances necessary for growth. Funk has termed these "vitamines" and ascribes to them certain specific growth stimulating properties. Röhmann does not subscribe to the theory of vitamines, but holds that the endosperm, which is the only part used in fine flour, is wanting in certain essential protein constituents—particularly those yielding lysin, arginin, and tryptophane. Just these essential constituents are, however, present in the protein substances found beneath the pericarp and which are available to man only in flour made from the whole grain, and specially in that which is finely milled. The use of such bread is therefore not only decidedly economical, but also provides a much more complete diet on the protein side.

Contemporary Comment

Insanitary Surroundings.—Those who are in charge of the public health of a city are in large measure responsible where epidemics take place that could be prevented, remarks the *Texas Medical Journal* for August. We look upon war as cruel and barbarous, which it is. The little children who are dying by the hundreds in this country from infantile paralysis—the latest scourge due to official neglect and public indifference—are murdered even more inhumanely than the men who stand blindfolded before the firing squads of an enemy. Will the physicians stand idly by, and by their silence approve a continuation of conditions which they know produce nine tenths of the epidemic sickness and deaths of the country? In the face of their knowledge of the causes that create such things, can they keep clear consciences without raising their voices unitedly in protest?

Officials become indifferent unless they are prodded to do their duty. The people generally are careless as to public health unless brought face to face with some appalling contagion, and even then they soon forget. Millions are so ignorant that they do not know anything about the causes that contribute to such things or how to stop them. The physicians are the volunteer guardians of the health of the people. It is no longer merely their duty to heal, but it is equally their obligation to prevent disease. How long will they, either as individuals or as organizations, neglect this self assumed duty? Every physician in the land should get behind the State, county, and city officials in such a way as to impel better conditions. They should talk to the people about them wherever they go, should instruct in sanitary improvement, should fill the press with warnings of the dangers, should personally entreat officials to be alert in conserving the health of the people, and point out the ways and means of bringing about improvement.

Elsner, Physician and Citizen.—To a heartfelt appreciation by Dr. Fielding H. Garrison, of Washington, D. C., of the late Henry Leopold Elsner, M. D., LL. D., of Syracuse, N. Y., Dr. Abraham Jacobi has added a characteristic tribute:

Dr. Henry L. Elsner was born in Syracuse, N. Y., August 15, 1857; graduated from the College of Physicians and Surgeons in 1877; became a teacher in the Medical Faculty of Syracuse University, which in 1915 honored him with the gift of the Doctorate of both laws; died in Washington, D. C., on February 17, 1916, and was buried in Syracuse, February 20, 1916.

Forty years ago, like Frederick Forchheimer, Elsner was my pupil in the College of Physicians and Surgeons of New York. No teacher ever had one more appreciative, progressive, grateful, and successful. European masters completed for the young man whatever was required for his perfection as a physician to the individual sick; as an adviser to countless distressed families; as a hospital organizer and attendant; as a friendly and superior consultant in the service of private colleagues and public institutions. No wonder he remained all his life the welcome guest of every sick room or hospital ward; the last hope of the working man, the farmer, the judge, the professor and the statesman; the forensic expert and sanitarian; the medical leader of the centre of the State, such as Dean had been, and Wey, and Ward. Probably no one leader has, to the same extent, remained to his dying day the adviser and the revered and blessed refuge of those whom he instructed and enlightened, and supported and encouraged, in the classroom, in the clinic, and in the hospital. I am sure there never were practical lessons in ethics like those taught by Elsner through his example in word and deed.

The presidencies of many local societies, that of the Medical Society of the State of New York, and his office in the House of Delegates of the American Medical Association, prove to those who survive him the honor we were all anxious to lay at his feet. By unceasing work and the many demonstrations of his wisdom and energy he rewarded the confidence we placed at his disposal.

The date of his return from Europe, within a year, was a festive day for the community, as the news of his death proved a signal for intense universal mourning over the loss of a great physician and fellow citizen. In both capacities he left his permanent impress. His Commonwealth has often relied on and gained by his practical wisdom: his profession, by his teaching in scores of his papers and essays. His last great book on *Prognosis in Internal Diseases* means more than that mere title. It comprehends etiology, symptomatology, diagnosis, and therapy—indeed, it means practical medicine. That one volume comprehends all that a great and good physician could learn, and study, and teach from history, observation, and experience. It will be a textbook for all, and for many years.

WATER WASTE.

There is little doubt that one of the greatest advances of modern times, as well as the greatest advance in preventive medicine, has been the rendering of the water supply more wholesome. The engineering and sanitary problems involved in solving this question have often been stupendous; new sciences of water engineering, water analysis, and water bacteriology have sprung up around this endeavor. No settlement can now thrive or even exist for any length of time without a wholesome water supply. The nature of water pollution is particularly human. Indeed, no other source of water pollution is of much moment, although waste from industrial enterprises often renders water unfit for drinking, but not in the sense of being disease carrying. One exception to the nonhuman source of disease carrying water is found in the goitrous waters of Switzerland and parts of Austria. Even the extensive water purification works had no effect in lessening the incidence of goitre and cretinism. Nevertheless, heating the water to 80° C. rendered it nongoitrous. Here it was believed that the elements in the water causing the pathological conditions were the remains of ancient marine animals or certain salts, both rendered inert by boiling.

Even the courts have favored the right of the individual to get his water unadulterated or unpolluted, even against the interests of large industrial enterprises or large communities. Communities have been held responsible in money damages for deaths resulting from polluted water. The plenary powers of the courts have been successfully invoked to enjoin further or even contemplated water pollution.

Human intestinal excreta are the most prolific causes of infection and pollution of water. The enormous morbidity from typhoid in this country as well as the epidemics of other intestinal diseases elsewhere is directly traceable to preventable water pollution. The Public Health Service has been carrying on extensive investigations of the pollution of the tidal waters. It intends to stop the many leaks which continue to keep the typhoid incidence so high. Most large cities have extensive plants for water filtration and the detection of water impurities. Perhaps the best test for the presence of an undue amount of human pollution in water is the presence of the colon bacillus. The expense of water purification is so large that many communities have refused the installation of these plants on this ground. Others have been forced to economize in this most expensive commodity—pure drinking water. The installation of water meters has served to bring home to the community that they are consuming an article whose cost of production is considerable. Yet even those centres which have an apparently inexhaustible water supply have been threatened with water famine during dry periods. Every growing community is continually worrying about the question of having an adequate and wholesome water supply. The city of New York, with this very problem in mind, has just finished a sixty million dollar water supply enterprise; but because of the rapid growth of some centres and the extravagant use of water there is no absolute safety. Economy in water offers perhaps the best assurance of safety. Upon the ample supply and reserve of the water supply the health, comfort, and progress of a community depend.

In Europe the use of water is on a more economical scale—perhaps too much so. Some places use as little as eight gallons per capita a day. It is estimated that from ten to fifteen gallons per capita a day is sufficient for all purposes. Yet in some cities in the United States as much as two hundred and fifty gallons per capita a day are consumed. It is true that included in this estimate is the water going to waste from leaky house fixtures, water mains,

and in industrial enterprises. Nevertheless, one half of the water supply in this country is wholly wasted. This may at any time become a serious problem. The supply must be conserved at all costs. The supply must be kept ample by stopping all sources of leak and by metering all water, as well as by bringing home to the public the necessity for economy. The waste of water in plenty may mean famine in leaner years, much to the detriment of the health of the community. Besides, the money thus saved could be appropriated elsewhere for the public welfare. The public should be made to feel the cost of water extravagance by paying for water they use. The purity and the adequacy of the water supply of a community must be as much a source of pride to the community as the beauty of its architecture or the physical development and health of its inhabitants. Like all advances in the field of preventive medicine and hygiene and public weal in general, the physician should act in the role of proselyter, and the need for active effort and influence in this matter is clear and imperative. Every physician is in duty bound to keep himself informed as to efficient performance of duty by the public officials who have in charge the supply and distribution of water.

THE RELIEF OF ANGINA PECTORIS.

Sufferers from angina pectoris are as well aware as their favorite physician of the extraordinary relief to be obtained from amyl nitrite. A London practitioner, Samuel Constable, apparently averse to the use of drugs in this condition, wrote to the *Lancet* for April 29, 1916, giving details of a new mechanical method of relief. His theory seems to be that minor attacks of angina are due to partial constriction of the vessels and major attacks to complete constriction. He had a friend, a Doctor X, who suffered from angina, and to him he paid a visit early in last December; he found him in much pain in both arms and chest. At once he got his friend to grasp the top bar of the bed with both hands, letting most of his weight fall on the now strongly stretched arms for some forty seconds. After a short rest he repeated the process some five or six times. Result: Immediate cessation of all pain in arms and some relief of the chest. Mr. Constable now got him on the floor to grasp the bar at the end of the bed with both hands behind his back, bending forward at an angle of about 60°, the chest thrown forward, and the head back, thus subjecting the muscles of the affected area to strong tension. This he repeated some half dozen times, each lasting about forty or fifty seconds. Result: Immediate cessation of all pains in the chest, the sense of constriction completely vanishing. He now went to his bath, and for the first time the exertion of washing caused only the merest suspicion of the old ominous forebodings of ill. For some weeks the process was continued about every two hours, the minor pains occurring with less severity and frequency; and it is important to note *that on no occasion did the stretching fail to give immediate relief*—the italics are Mr. Constable's—though the operation must have been performed hundreds of times. No medicine was taken. Doctor X is now at work and able to walk with almost his old rapidity.

Mr. Constable gives details of equally gratifying results in two other patients, one a man aged thirty-five years, the other a French polisher, fifty-two years of age. The latter described his sensation of comfort as accompanied by a tingling and rushing of blood over his face and neck. Mr. Constable believes that worry is the great predisposing cause, while the pain he attributes solely to the atheroma. As asthma is believed to have a similar origin, perhaps dietetic and hay fever asthmatics might obtain relief from their paroxysms by carrying out the same or similar procedures.

THE PATHOLOGICAL ACCOMPANIMENTS OF MENTAL STRAIN IN WARFARE.

Just as mental disease appears to be a growing menace coincident with the more complex requirements of civilization, so does any increase in the tensity of national affairs show a corresponding addition to the number of mental diseases. It was only to be expected that the present war would prove no exception to this rule. The reports which reach us from the firing lines describe conditions which prevail there by such terms as "inferno," "hell on earth," and "orgy of death." Surely it is small cause for wonder that some of the men forced to live through such scenes should succumb under the strain, and that those who are predisposed by reason of some psychopathic determinant in their heredity should manifest psychoses.

In the *British Medical Journal* for March 25th, Dr. R. G. Rows called attention to some of the mental conditions found at the front, as observed at the Red Cross Military Hospital, at Maghull. It seems that most of the men who broke down under the stress and were found to have psychoses and psychoneuroses, could be definitely proved to be neurotic; some had had distinctly psychotic attacks in earlier life. Not infrequently the history was of a mild psychotic episode years before with inadequate recovery. By inadequate recovery is meant that the patient instead of adjusting his mental conflict, compromised by leaving the scene. Then he drifted

into the army with his mental trouble still dormant. One of these men accidentally shot a comrade; another had a friend shot dead at his side. Shocks of this kind brought back the psychotic symptoms.

Doctor Rows takes an enlightened view of the problem. He thinks that the mechanism of simple mental process should be described to the patient in plain language, and the emotional affect accompanying psychic events and its persistence in the unconscious be explained in understandable terms. In short, a psychic catharsis should be attempted. He believes also that a special hospital with an efficient staff should be devoted to work of this sort.

SANITARY FOOD HANDLING.

There is no factor of quite the same importance in the spread of disease as the ingestion factor. Many of the diseases formerly thought to have arisen in some unknown and miraculous way, are now definitely shown to be spread by ingestion of infected food products or of infected drinking water. The list of diseases so spread is hardly complete with tuberculosis, typhoid, cholera, dysentery, worm diseases, and the like. About fifty per cent. of all tuberculosis of childhood is of bovine origin, and, therefore, is ingestion tuberculosis. While drinking water is still accused of being the most prolific cause of typhoid fever, it probably is the least, for the reason that the typhoid bacilli in drinking water reaches the consumer much diluted, and because of its exposure therein is much attenuated as to virulence. On the other hand, infection carried to exposed food by unclean hands, or by flies which have perhaps alighted on or fed on infected human excreta, offers the readiest and the best method of infection. In a similar manner, the pernicious habit in some communities of spraying gardens with human excrement offers the richest possible source of infection. Faulty methods of sewage disposal in rural communities act to the same end. Surface soil pollution is a direct source of food infection as well as of pollution of drinking water.

However common food infection may be through faulty methods of cultivation or handling at the source, it may be overcome to a large extent by care in preparation. It is of no advantage that at some sources food is cultivated and handled properly if later it is to be rendered unfit by uncleanly preparation, or if diseased food handlers are to become means of transmission.

One of the largest abuses is the consumption of raw vegetables without proper cleansing. Indeed, because of this it is often not safe to eat raw vegetables, salads, or fruits, where kitchen methods are lax. Gritting of sand between the teeth while eating vegetables raw is a certain sign that they have been cleansed improperly, if at all. In countries where amebic dysentery is endemic vegetables are never eaten raw because the difficulty of properly washing them is recognized. In such localities, to contract dysentery is a certain indication that these elemental precautions with regard to raw food have not been observed. In cholera epidemics of the past the drinking water was indicted almost solely as the source of infection, but there is little doubt that infected food played an equal role.

The public is dependent in a large measure on the preparer of the food, especially in public eating houses, to destroy much of the unavoidably infected food, and must especially trust to him to use such sanitary precautions as will reduce to a minimum the transfer of infected materials to the food. Scientific food handling and food preparation can be made to accomplish this economically. As a factor in maintaining the public health and in preventing the spread of disease the public eating place is perhaps the most important, and no amount of stringency in its sanitary regulation can ever be accused of being unwarrantably oppressive.

THE PHYSICIAN'S VACATION.

The physician above other men needs a vacation, a change of scene and occupation. He needs it even if he is not a "busy" practitioner, and indeed almost in proportion as he is not busy, for the man who has recently hung out his sign, and the physician longer in practice whose time is none too full of professional work, have often more of stress and worry, conscious or subconscious, than their very successful brethren. There is such a thing as taking recreation the year round by losing one's self as occasion offers in work other than professional—in equestrian performances on one's hobby. There is rest and pleasure in variety of labor, but a complete change of place, board, and occupation is often needed also in order to put a new edge on living. The city physician finds it comparatively easy to absent himself from his office for a few weeks. Others do this, and his clientele expect to find him absent for a season each year. Besides, he may choose among many to look after his patients, without detriment to his business, while he is absent. In the village or country, it is different. Patients take it as an affront to find their physician absent, and have been known to dismiss him for his selfishness in leaving them in the lurch when they were about to be attacked by dyspepsia, or their children by the chicken pox. Perhaps the physician, or physicians in general, may be largely to blame in not educating the people to expect them to be away for a time and to leave their

patients to the kindly attention of a brother physician, who may desire a similar service at another time.

It seems to be proved by a number of recent studies that we need our vacations from work chiefly in midwinter, but for most physicians the winter season is out of the question. Besides, the country or shore, whither we ought usually to go for recreation, offers its abundance of joys in the summer season. Still, if one is worn and feels the need of a change, the season may be neglected and a sojourn in the great city, or the south, will afford the needed change. It goes without saying that the physician will not obtain rest through doing foolish things in his vacation, as so many of the laity seem inclined to do. From experience with patients he ought to be so sensible in his recreational behavior as not to need a vacation from a vacation. To sleep o' nights—and maybe a part of the day for a season—and to be far removed from the ring of the telephone, is in itself worth all the cost of the lost calls it may entail.

WHOLE WHEAT FLOUR.

An interesting excerpt on the use of whole wheat bread is printed in our department of Dietetics in this issue of the JOURNAL. In view of the fact that ordinarily it is difficult or impossible to obtain freshly ground whole wheat flour, it may be valuable to know that it is quite possible to obtain at small expense a practical household mill for grinding wheat. A small grinder in the kitchen may be used not only for supplying whole wheat flour for the family, but also for cracking wheat, corn, barley, oats, rye, and other grains for use as breakfast cereals. These should be obtained from a seedsman rather than from a grocer or feed store, because in this way a high quality of clean grain is insured at small cost. Flour may be also ground from any of these grains. In this way persons who need to have the benefit of unadulterated natural cereal foods can supply themselves at minimum expense. Moreover, there is an additional advantage in providing in our emasculated city homes a means for exercising the deltohumeral muscles of developing adolescents in the household; in other words, the children may be allowed the privilege of grinding the grain. The fireless cooker should be kept in daily use if these cereals are to be prepared most appetizingly and by truly scientific means.

TREATMENT OF IVY POISONING.

Studies of Rhus toxicodendron show that its poisonous principle is a volatile acid resin; therefore, the treatment of rhus poisoning with an alkali is theoretically right. In practice the correctness of the theory is borne out; a saturated aqueous solution of sodium bicarbonate being one of the most efficacious remedies. Recently a note was made in these columns of the application of ice water for rhus poisoning in the United States Army with good results. The possibility of combining the alkaline and ice water treatments naturally suggests itself, and upon trial this has been found to be prompt and efficacious. In two cases which have come to our notice a saturated solution of sodium bicarbonate in ice water applied freely and continuously to the infected area brought about prompt relief and a complete cure within twelve hours. In view of the suffering entailed by a severe attack of rhus poisoning and of the failure of the older methods of the treatment with opium and lead water, grindelia, etc., it is well to bear in mind this method, which is easy of application and prompt in affording relief. We should be glad to hear reports from any of our readers who may try this method of treatment.

News Items

American Hospital Association.—The eighteenth annual meeting of this association will be held in Philadelphia, September 26th to 30th, with headquarters at the Bellevue-Stratford Hotel. A feature of the meeting will be an exhibit of hospital supplies.

The Cartwright Lectures.—These lectures, which are given under the auspices of the Alumni Association of the College of Physicians and Surgeons, Columbia University, will be given on October 24th and 25th by Dr. Richard M. Pearce, of the University of Pennsylvania, his subject being The Spleen in Its Relation to Blood Destruction and Regeneration.

Personal.—Dr. Abraham Jablons announces that he has opened an office at 219 East Twelfth Street, between Second and Third Avenues, New York.

Dr. James J. Mills, instructor in ophthalmology at Johns Hopkins Medical School, Baltimore, sailed for France recently, for the purpose of assisting in the treatment of eye injuries of soldiers.

Tuberculosis Week.—The National Association for the Study and Prevention of Tuberculosis announces that Tuberculosis Week this year will be observed from December 3d to 10th. Attention is directed to three special days indicated for this week, namely, National Medical Examination Day, Wednesday, December 6th; Children's Health Crusade Day, Friday, December 8th, and Tuberculosis Sunday, Saturday or Sunday, December 9th or 10th.

The Poliomyelitis Epidemic.—A report issued by the health department shows that on Wednesday, August 23d, there were reported in New York City 131 new cases of poliomyelitis, with 42 deaths; on Tuesday, there were 118 cases, with 39 deaths. The daily average of new cases last week was 134; for the first three days of this week the average has been 114, which indicates that the epidemic is declining. The total number of cases to date is 7,315, with a total of 1,689 deaths.

The Psychopathic Clinic at Sing Sing.—Dr. Bernard Glueck, of the Government Hospital for the Insane, Washington, D. C., has been appointed psychiatrist in charge of this clinic, which was established recently at Sing Sing Prison, Ossining, N. Y. He will devote his entire time to the work and will be supplied with the necessary assistants. The work will be under the immediate supervision of an advisory board of the National Committee for Mental Hygiene, which is composed of the following members: Dr. August Hoch, director of the New York State Psychiatric Institute; Dr. William Mabon, medical director and superintendent of the Manhattan State Hospital; Dr. William L. Russell, superintendent of Bloomingdale Hospital; Dr. George H. Kirby, clinical director of the Manhattan State Hospital; Dr. L. Pierce Clark, consulting physician to the Institution for the Feebleminded at Randall's Island; and Dr. Thomas W. Salmon, medical director of the National Committee for Mental Hygiene.

New Hospitals in Argentina.—The Argentine Government has recently accepted tenders for the construction of two new hospitals, one at Posadas, Territory of Misiones, and the other at La Rioja. The hospital at Posadas, to be known as the Hospital Común Regional de Misiones, is to be constructed at an expenditure of $136,529, and the hospital at La Rioja, which is to be called the Hospital Común Regional Andino, will cost $208,390.

New York and New England Association of Railway Surgeons.—The twenty-sixth annual session of the New York and New England Association of Railway Surgeons will be held at the Hotel McAlpin, New York, on Wednesday, October 18, 1916. A very interesting and attractive program has been arranged. Dr. William S. Bainbridge will deliver the Address in Surgery, his subject being the Cancer Problem. Railway surgeons, attorneys, officials, and all members of the medical profession are cordially invited to attend. Dr. D. H. Lake, of Kingston, Pa., is president, and Dr. George Chaffee, of Little Meadows, Pa., is corresponding secretary.

Poliomyelitis in Buffalo.—According to official reports of the Buffalo Department of Health, up to July 31st there had been reported only two cases of infantile paralysis in Buffalo with one death. This report contained the following résumé of this disease in Buffalo during the past: In 1910, fifty-two cases with five deaths; in 1911, nine cases, no deaths; in 1912, 316 cases with twenty-three deaths; in 1913, seventeen cases with three deaths; in 1914, nine cases with two deaths, and in 1915, thirty-one cases with five deaths. Since 1912 the Health Department, with the consent and assistance of the attending physician, sent a physician and a nurse to every case of poliomyelitis for the purpose of giving the mother instructions in the proper care and treatment of the patient. This was continued as long as seemed necessary.

Gifts to Hospitals.—The trustees of Flushing Hospital, Long Island, announce a gift from the three daughters of the late Dr. and Mrs. Joseph L. Hicks, of a trust fund of $5,000, the income of which is to be used toward the support of a bed in the hospital to be called the Hicks Bed. The bed is established in memory of their parents, who were active in the work of the hospital.

By the will of James Hay, late of Philadelphia, the Episcopal Hospital will receive $25,000 and the Home for Incurables, $5,000.

By the will of Fanny Brown, the Presbyterian Hospital, of Philadelphia, will receive $10,000.

Two bequests to the Presbyterian Hospital, New York, amounting to $350,000 are contained in the will of the late Charles W. Harkness.

Civil Service Positions in State Institutions.—The New York State Civil Service Commission calls attention to the opportunities offered to qualified physicians for appointment to positions in the medical service in State hospitals, prisons, and charitable institutions. Although the salaries offered seem to afford adequate compensation the number passing the examinations has not been sufficient to meet the needs of the service. An examination was held recently for prison physician, salary $2,000, but the number of competitors was very small and no one passed the examination. An examination for assistant physician in the prisons, salary $1,500, held at the same time, produced only two eligible persons. An examination for assistant physician in the State hospitals held January 22, 1916, produced eighteen eligible persons, but the list was practically exhausted before July 1st. Another examination was held July 15th, but only eleven competitors were secured. This position carries an initial salary of $1,200 with maintenance, including quarters, board, laundry, etc., and the salary is automatically increased $100 a year until $1,600 is reached, when opportunity is offered for promotion to the next higher grade, senior assistant physician, at 1,800 and maintenance. The State Hospital Service really offers a career, as there is a regular line of promotion for the medical staff from assistant physician to the position of superintendent. Any one interested in these examinations should write to the State Civil Service Commission, Albany, N. Y., for information.

A Paralysis Hospital at Garden City.—A temporary hospital for the reception of infantile paralysis patients was opened on Hempstead Plains, near Garden City, Long Island, on Thursday, August 17th. The hospital is designed to meet the needs of the community until the health authorities of the county have provided adequate accommodations. It has been established by popular subscription, about $2,500 having been raised to meet the expense of opening and equipment, and it is understood that the residents of Garden City will meet all further demands for money. Dr. Louis Lanehart is in charge of the hospital, which is a metal structure and will accommodate five patients.

Hospital Ship for the Sulu Archipelago.—The International Health Board of the Rockefeller Foundation has entered into a cooperative agreement with the Philippine Government for the equipment of a hospital ship for the Sulu Archipelago, and its maintenance for five years. The inhabitants of the Sulu Archipelago are scattered over a large number of islands and the establishment of dispensaries at various points would reach only a very small fraction of the population. To meet the situation this hospital ship is being provided. It will be expected to go from island to island meeting the people at established points, bringing medical relief to the afflicted, training midwives, and giving general iinstructions to the people. Preliminary investigation shows that the medical needs of the people are great. They suffer from malnutrition and from diseases which are fostered by filth and negligence. The common diseases are skin diseases in their worst forms, malaria, hookworm disease, dysentery, and other preventable infections.

Tuberculosis Conference.—Sectional conferences on tuberculosis will be held during the month of October in New Haven, Conn.; Louisville, Ky.; Jackson, Miss.; Newark, N. J., and Albuquerque, N. M., under the auspices of the National Association for the Study and Prevention of Tuberculosis. The Louisville conference, which will comprise the Mississippi Valley States, will meet on October 4th, 5th, and 6th. The New England States Conference at New Haven will meet on October 12th and 13th; the Albuquerque Conference, taking in the Southwestern States, on October 13th and 14th; the North Atlantic States Conference at Newark on October 20th and 21st, and the conference for the Southern States at Jackson, Miss., on October 30th and 31st.

The governors of every State in the territory of each of these conferences will appoint delegates, and the mayors of practically all of the principal cities will send representatives. Chambers of commerce, State and county medical societies, antituberculosis associations, women's clubs and other civic and social groups are being urged to send delegates to the conference in their various districts. The programs of each conference will be suited to the locality in which the conference is held. Speakers of national prominence will be present at these meetings.

Poliomyelitis Ward in Bellevue Hospital.—In order to care for the great number of cases of poliomyelitis, Bellevue Hospital has been obliged to open a special ward for the treatment of acute cases, where there are now some eighty patients, and a second ward to which they are transferred when convalescent from the acute attack, where there are now over fifty patients. This convalescent service is in charge of the neurological and orthopedic departments of the hospital, and furnishes a remarkably large field for the study of the disease and its results, and the benefits to be derived from suitable treatment.

The amount of work necessary to intelligently care for this increased number of patients has made necessary an increase of the personnel of the house staff, and there is at the present time a position open for a graduate physician in this poliomyelitis ward where he will receive board and lodging in the hospital during the period of his service, which would be a six months' term, and could be supplemented by a further period of six months if desired. Application should be made to the Superintendent of the Hospital, Dr. George D. O'Hanlon. Preference will be given to applicants having previous hospital experience, but the latter is not necessary. The facilities offered for the study of this little understood malady are so great that there should be no difficulty in filling this position.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirty-fourth Communication.

ARTICULAR RHEUMATISM.

Our meagre knowledge of the etiology and pathology of rheumatism avails little in determining a rational therapeusis. Excluding infective arthritis, with which acute articular rheumatism is often confounded, it is yet unknown what so alters synovial and serous membranes as to give rise to serofibinous exudates. There is warrant for the belief that there exists primarily a hemic dyscrasia, and all attempts at treatment must consider this presumptive causative factor even while seeking to alleviate the symptomatic misery.

In most cases there seems to be reduction of the alkalinity of the blood; this is best met by administration of sodium bicarbonate. A great deal of this alkali will be changed in the stomach to the chloride, but some of it presumably passes into the bowel, where it is taken up by the blood stream; even its decomposition in the stomach may be considered advantageous through the stimulation thereby of acid production by consuming the acid carbonates of the blood. The quantity of sodium bicarbonate required will be an amount necessary to keep the urine continuously alkaline.

Many clinicians report amelioration of distress in articular rheumatism by use of the salicylates, although in what manner pain or fever is affected by this drug is unknown. It seems certain that beneficial results frequently follow use of the salicylates, but it seems equally probable that many favorable reports represent inadequate observation. Possibly the salicylates neutralize to some extent the hypothetical toxin present in the blood stream, without accelerating elimination to any great extent. It is claimed that salicylates tend to prevent cardiac complications, and this may be a justifiable claim, if it is true that this drug really neutralizes toxins in the blood stream. Belief in such a prophylactic action is at present based on a purely gratuitous assumption, yet is one which might be embarrassing for the average physician to ignore.

An important part of the treatment is to secure rapid elimination of the hemic toxins by hemoclysis. The patient may be given hot drinks, in quantity; extra warm and large saline enemata may be administered slowly; saline solutions may be injected hypodermically; the patient may be sweated freely; the whole object being to promote as rapid metabolism in the blood stream as may be judiciously possible. Frequent cleansing baths in warm water are also desirable, not only for the comfort of the patient and his attendant, but also to maintain the skin in a condition favorable for free diaphoresis.

Local medication can be of but little utility. Especially delusive is the local use of any opium preparation, inasmuch as opium acts sedatively on the sensorium only, and is absorbed but little from the unbroken skin. Sometimes counterirritation exerts a favorable influence through its stimulating influence over a reflex path; and occasionally either hot or cold fomentations serve a similar purpose. Chronic inflammation of the joints is often relieved by hot air treatment, by which local circulation is hastened, and the reflexes are intensely stimulated. But it must be admitted that at present the pharmacologist can offer little aid to the therapeutist in the consideration of rheumatism.

Results Obtained with Carrel's Method in the Treatment of Wounds.—M. Perret (*Bulletin de l'Académie de médecine,* April 11, 1916) states that mere inspection, revealing a great variety of dirt carrying substances in the average wound by a military missile, is sufficient to convince one of the infected condition of these wounds, as a class. Two important points in the application of Carrel's treatment are, 1, that the wounded must be treated within six hours after the reception of the injury, and, 2, that the wounds must be widely opened up and entirely freed of all foreign substances before the irrigations with Dakin's fluid are begun. Within a period of about four months there were treated with Carrel's method under Perret's supervision 111 wounds of intermediate or pronounced severity, comprising seventy-eight wounds of the soft parts and thirty-three involving bones. In the former group complete disinfection was attained in three or four days, repair then following with extraordinary rapidity. Some wounds healed in ten days. In the case of a man who had sustained a perforating wound of the left thigh, a long abdominal erosion, and a broad, deep laceration of the right thigh, with hernia of the torn muscles and metallic fragments disseminated in the tissues to a depth of six centimetres, treatment of the wound by Carrel's method, after proper removal of foreign bodies, resulted in the patient's discharge in three weeks and his return to the front a week later. Wounds thus dealt with present a bright red color, never suppurate, and exhibit no odor or inflammatory reaction; the initial high temperature drops rapidly to normal. Compound fractures of the upper extremity healed very readily; two fractures at the elbow, for example, undergoing repair without fever at any time. The compound fractures of the lower extremity included injuries of the knee joint, comminuted thigh fractures, and fractures of the leg. The entire series of 111 patients is now recovered and in good health. No amputations were necessary, their principal cause, infection, having been eradicated. The statement may thus be boldly made that wound infection has now been mastered. Whether fluids other than Dakin's solution might yield the same results the author does not know.

Acute Frontal Sinus Headache.—Hugh B. Caffey (*Jour. Kansas Med. Society,* July, 1916). This condition is very commonly encountered by the general practitioner in epidemics of grippe and colds in the head and usually responds promptly to simple measures. The turbinate body should be gently massaged with a cotton tipped probe soaked in a two per cent. solution of cocaine and epinephrine. These applications should be followed by the use of an alkaline wash or the application of argyrol. The use of aspirin, codeine and quinine may often be added to the general treatment with decided benefit. The treatment of the nose should be repeated daily as long as the headache continues.

Radium Treatment of Epithelioma.—Thomas C. Kennedy (*Journal of the Indiana State Medical Association,* July 15, 1916) says that while radium is not a cureall, it will cure every case of epithelioma that is amenable to treatment. When used intelligently it is a painless, safe, and efficient method of treating malignant skin affections, and is to be preferred in epithelioma of the face. The number of treatments varies; improvement usually is noticed after two or three exposures, and frequently after the first. The analgesic action is marked and is frequently noted after the first application. It is held by some physicists that there is a decided difference in the physical properties of x ray and radium. The latter has cured cases in which the former had failed.

Intravenous Treatment of Tetanus.—C. H. Browning (*The British Journal of Surgery,* July, 1916) states that in the treatment of tetanus intravenous administration produces the most rapid action; Straub employs a 2.5 per cent. (i. e., isotonic) solution; from fifty to 150 c. c. should be injected in two minutes. Spasm relaxes in from one to five minutes, but the effect passes off in half an hour. On account of the effect of intravenous injections on the heart, Meltzer urges caution in the use of this method, and recommends injecting a six per cent. solution at the rate of from two to three c. c. per minute; slowing or shallowness of respiration is an indication for immediate discontinuance of the injection; if this does not cause prompt improvement, inject slowly through the venous cannula a small amount of 2.5 per cent. calcium chloride.

Treatment of Erysipelas with Diphtheria Serum.—H. Koller (*Correspondenz-Blatt für Schweizer Aerzte,* July 8, 1916) reports a case in which a woman sixty years old was suffering from a severe attack of erysipelas, and great improvement followed the administration of diphtheria serum. The first dose of 3,000 units was given April 15th. The next day five c. c. of electrargol were given by intravenous injection. On the seventeenth the second dose of the serum, 1,000 units, was given, and by the next day the patient was practically well. The course resembles closely that of a case reported by Pollak in 1915, but the extent to which it was influenced by the serum cannot be said to be proved. Koller emphasizes the advantage of using electrargol in combination with it, and says that they work together harmoniously, but to which the result is to be attributed is not clear.

Treatment of Chlorine Gas Poisoning.—A. Stuart Hebblethwaite (*Brit. Med. Jour.,* July 22, 1916) has found that the type of poisoning with chlorine, in which the patients were cyanotic and much distressed but preserved a good pulse, was found to require more effective treatment than the administration of atropine and the inhalation of ammonia. In these venesection was tried with very beneficial effects, bringing great relief of the cyanosis and pulmonary congestion, relief from the acute headache and the production of sleep with marked refreshment upon waking. To be successful the venesection should be performed early, and from fifteen to twenty-five ounces of blood should be removed, depending upon the robustness of the patients. Early bleeding greatly spares the heart from the effects of strain due to the pulmonary congestion, but in some individuals cardiac stimulants will be required, following the venesection.

Magnesium Sulphate in Delirium Tremens.—Edward A. Leonard (*Jour. A. M. A.,* August 12, 1916) states that lumbar puncture should be performed and ten to forty c. c. of spinal fluid withdrawn. Following this one c. c. of a twenty-five per cent. solution of magnesium sulphate should be injected for each twenty-five pounds of body weight. The withdrawal and injection should be made with the patient in the sitting posture and he should then be lowered to one of semi-recumbency. Nearly constant attention is required for twenty-four hours after the injection to secure nourishment and proper care of the bladder and rectum. The treatment produces prompt relaxation and often a paraplegic state which begins to disappear in twelve to twenty-four hours. Complete restoration of function and reflexes usually occurred in thirty-six to forty-eight hours, and the patients were then permanently free from their delirium and restlessness. Twelve cases were treated thus, only one injection being required in any case. Ten recovered and two died, a great improvement over the results of the usual methods of treatment.

Radical Treatment of Gastric Ulcer.—Joseph Cunning (*Lancet,* July 22, 1916) claims that the operation of gastro-jejunostomy is not curative and often leads to the development of conditions quite as bad as those which it has undertaken to relieve. Its mortality is not inconsiderable. In view of these facts the author has long practised the more formidable operation of excision of the ulcer. In some cases he has performed a total pylorectomy with anastomosis between the duodenum and the fundus. Some cases, however, were encountered in which neither of these operations could be performed on account of the close adhesion of the ulcer to the pancreas or other organ. For these a new plan was adopted, namely, detachment of the stomach from the adhesion by an incision encircling the entire ulcer. The opening thus made into the stomach was closed and the exposed ulcer scraped and left in situ to undergo healing, no attention being paid to the possible formation of adhesions. This new method gave most satisfactory results and the author has had no deaths following either this or the simpler operation of excision.

Heliotherapy in Chronic Suppurative Osteoarthritis of the Elbow Following Fracture.—R. Bayeux and J. Vallot, at a meeting of the Société de pathologie comparée (*Presse médicale*, June 29, 1916), reported a case illustrating the powerful disinfectant and healing action of sunlight, not only at the skin surface, but also deeper in the tissues. The treatment should be administered in the open air, for glass arrests the ultraviolet rays which are beneficial in this direction. The effect is more pronounced, moreover, in a warm than in a cool atmosphere, and the treatment should be given high above the ground, in a place free from dust. Experience is required to appreciate properly the activity of the sun's rays at a given place and at a certain time of day. Slow, progressive pigmentation is the best criterion of a favorable therapeutic action. On the first day only one half hour's exposure to the sun is indicated. This may then be augmented by ten to thirteen minutes daily up to a maximum of two hours.

New Remedy for Diarrhea.—M. Cloetta (*Correspondenz-Blatt für Schweizer Aerzte*, July 22, 1916) suggests the administration of a colloidal hydroxide of aluminum to take the place of bismuth, which has risen much in price. He states that this preparation passes through the stomach without being dissolved, to become dissolved gradually in the intestine, where it is not absorbed, but exerts an astringent action. He recommends it on the grounds that theoretically it is a correctly constructed remedy for diarrhea, and that through its prescription in the place of other preparations advantage will accrue to the medical service of the Swiss army. Erich Liebmann, in another paper on the same subject in the same journal, reports several cases in which this remedy, described under the name alutan, produced excellent results. He thinks it a useful remedy in many cases of diarrhea from various causes. The dose he suggests is from two to three tablespoonfuls daily, given in water or milk. The only unpleasant consequence is vomiting, which occurred in two cases.

Hay Fever: Its Treatment with Autogenous Vaccines and Pollen Extract.—Leon S. Medalia (*Boston Medical and Surgical Journal*, August 10, 1916) reports six cases of hay fever treated with autogenous vaccines. The results given are encouraging. The cultures were obtained by passing a sterile swab along the floor of the nose to the posterior wall of the pharynx in such a way as to wipe off as much of the mucous lining of the passage as possible during the withdrawal, and then, implanting in the ordinary way on glucose agar, blood serum, bouillon, and blood agar. Several tubes of glucose agar slants are used, sufficient for an autovaccine. Cultures are also made from the throat by swabbing off the tonsils, going as deeply as possible between the pillars of the fauces, and from the conjunctiva by placing a swab upon it, covering it with the lids, and having the patient squeeze the lids tightly, so as to have the swab soak up any secretion present. As a rule the growth was found sufficient for the preparation of autogenous vaccines at the end of twenty-four hours, and these were made in the ordinary way. Four of the cases were treated with pollen extract alongside of the autogenous vaccines, but the results obtained from the vaccines alone, as well as from the combined method, and the way these same cases reacted to the vaccines prior to the use of the pollen extract, make the author feel that the pollen extract can be dispensed with. One case of hay fever and asthma of over twenty years' standing has been under observation since March, 1911. The relief in response to the autogenous vaccine was marked. The patient needs two or three treatments each year, which produce no discomfort. She has had no asthma practically from the beginning of the treatment, and has been free from hay fever, with the exception of a slight transient attack of sneezing following a long automobile trip. This the writer believes to be the only case of hay fever on record in which autogenous vaccine has been used for such a length of time. No pollen extract was used in this case. It is worth noting that four of the six cases gave a family history of hay fever, which is confirmatory of the suggestion already made that there is a hereditary predisposition to this disease.

Treatment of Inoperable Cancer of the Breast.—C. W. Strobel (*Medical Record*, August 12, 1916) describes a method used by him in sixteen cases since 1898. It consists briefly of four stages: Denudation, removal, skin grafting, and finally lymphangectomy, radium and x rays. The first stage destroys and removes all the skin layers, with the underlying fascia as well as the nipple, and is done by crayons of potassium hydroxide. The second stage destroys and removes all mammary and adjacent infected tissues, from the midsternal to the midaxillary line and from the 2nd to the 7th rib. This stage is accomplished by a compound of zinc chloride, sanguinaria root, and willow charcoal. The skin grafting is done with skin from the patient's thigh to hasten convalescence, minimize contractures, and secure a freely movable skin.

A Few Suggestions for the Treatment of Fractured Jaws.—A. C. Valadier (*British Journal of Surgery*, July, 1916) points out that the treatment of an ordinary fracture of the jaws, such as we meet in times of peace, is an easy matter for the oral surgeon; but the wounds caused by gunshot, with which we come into contact at the present time, require special consideration on the part of the operator. Wounds caused by bullet or shrapnel will generally be complicated; that is to say, a piece of metal may lodge in a most vital spot. The following points have then to be determined: 1. Whether or not it is right to attempt immediate removal of the foreign body? 2. Whether the patient will stand the strain of an anesthetic? 3. Whether the region of the glottis may be so inflamed as to contraindicate the use of a general anesthetic? 4. The patient's oral cavity may be so lacerated that food cannot be introduced. Should he be surgically treated at once to overcome this condition, or should prosthetic interference for the reduction of his fractured jaw be applied before surgical interference? These questions are of the utmost importance, and can only be answered by the oral surgeon in charge.

Treatment of Acute Articular Rheumatism.—Aygusto Fantoni (*Gazzetta degli Ospedali e delle Cliniche*, July 20, 1916) maintains that this condition must not be looked upon from an etiological standpoint as a disease *per se*, but rather as a manifestation of a particular mode of action of many pathogenic microorganisms. The salicylic treatment, while specific, is incomplete and sometimes harmful. Fantoni recommends a powder containing: Aspirin, 7.5 grains; quinine salicylate, 1.5 grains; caffeine, one grain, and camphor, 1/10 grain; every half hour for five to seven doses. Intravenous injections of mercuric chloride are a rational procedure and shorten the disease in addition to preventing sequelæ.

Intravenous Injections of Colloidal Sulphur in Acute and Chronic Rheumatism.—R. Massalongo and S. Vivaldi (*Riforma Medica*, July 16, 1916) state that the treatment of thirteen cases by this method would show that the intravenous injection causes a short chill, followed by fever which quickly subsides with profuse sweating. Immediate and marked improvement in the patient's general health is seen, with rapid diminution of pain and shortening of the morbid process. They counsel its use in young and robust patients without visceral complications, where salicylic treatment has been without avail. The pharmacodynamic action of the sulphur is obscure, but it is analogous to that of other colloidal metals, especially gold. It would seem that this action in rheumatism is by thermic elevation and consequent intense diaphoresis.

Treatment of Pneumonia.—J. Watkin Edwards (*Brit. Med. Jour.*, July 22, 1916) advocates in a paper on industrial disease the following plan for treatment of pneumonia which has proved most satisfactory in his hands. The patient should be kept in bed in a warm, sunny room with plenty of circulating fresh air, but no draughts. The bed clothes should be light but warm, and the lower extremities should be tucked in with blankets and a paper or rubber sheet. A cotton-wool jacket may be used on the chest, but should permit easy examination and sponging without too much disturbance. Poultices should not be used, but the skin should be sponged daily and camphor oil rubbed over the chest to relieve pain, promote the circulation and comfort the patient. Serum or vaccine treatment has not been very successful and has not yet won a definite place in the therapy of the disease. For the first three or four days water, lemonade or weak tea to the extent of three or four pints in twenty-four hours is about all that should be allowed. After this hot milk and hot beef tea may be given alternately every three hours and milk sugar may be added to the lemonade. An initial dose of calomel should be given and this may be repeated when needed, with or without a saline laxative. The prevention of constipation, restriction of the diet and the administration of an abundance of water are the best measures to prevent meteorism. Large doses of the acetate or citrate of ammonium should be given from the beginning to promote the free action of the skin and kidneys. Constant tepid sponging best relieves the high fever and for pain the use of small doses of aconite and antimony is often helpful. Dover's powder, gray powder and quinine in powder or capsule is useful treatment for the pain. Leeching or cupping may also be helpful. Where there is toxemia more water should be given and diuresis and diaphoresis should be promoted, and in alcoholic cases a mixture of potassium iodide and creosote gives good results. The amount of warm air and of sunlight should be increased and ammonium carbonate and strychnine, with or without digitalis, should be provided in the face of circulatory failure. Reliance upon the general measures of care and nursing is better for sleeplessness than upon the modern soporifics. A small dose of morphine may be required at bed time in some cases, and when he is comfortable the patient should not be disturbed for anything during the night.

Drug Addicts and Their Treatment.—T. D. Crothers (*Medical Record*, August 5, 1916) considers hospital treatment to be the first essential in most cases and that substitutes of the narcotic family are dangerous, and sometimes are worse than the original drug. Elimination is necessary by the skin, the bowels, and the kidneys. Mineral baths are most useful whether they contain soda, salt or gas. Symptoms and conditions concealed by the drug and which come to light upon its withdrawal are important. The central fact is that drug addictions are distinct neuroses and psychoses and are amenable to treatment and curable. The rapid cure would seem to be the best by means of excessive purgation, bathing, rubbing and the drinking of large quantities of water, as there are no symptoms of the expected shock. However there is certain to be reaction in such cases, in a tendency to recurrence of the habit. This method is suitable only in a certain percentage of cases; gradual withdrawal is indicated in others—the proper method must be determined by the physician in each individual case.

Vaccine Therapy in Chronic Bronchitis.—H. A. Cables (*Lancet-Clinic*, July 22, 1916) lays stress on the adequate differentiation of chronic bronchitis with abundant sputum from pulmonary tuberculosis, and calls attention to the efficacy of vaccine treatment in the former. In chronic inflammation of the finer divisions of the bronchial tract there is a great tendency to localization and, to some extent, one is able to determine the causative agent, e. g., the streptococcus, staphylococcus, or influenza bacillus. The streptococcic form is usually more widespread than the other varieties, and is manifested in afternoon fever and tachycardia, night sweats, loss of weight, and mucopurulent yellowish or greenish yellow sputum. Differentiation from tuberculosis is at times only possible by painstaking examination of the sputum, by the tuberculin test, and by carefully considered physical findings. The staphylococcic type is generally more localized and the symptoms are less severe. In the treatment, Cables uses stock vaccines of the Van Cott formula. The first dose given is a large one, to excite the formation of a great amount of antibodies. The interval between doses is always at least four days, and is lengthened to a week or ten days as improvement takes place. Codeine, one quarter grain every two hours, is often given to procure temporary relief before the action of the vac-

cine is brought into play. A typical dose of vaccine contains fifty million streptococci, one hundred million each of colon bacilli and pneumococci, and five hundred million staphylococci. The improvement following each dose depends upon the severity of the reaction, which is partly local and partly systemic. Histories of cases are given illustrating the benefit obtained. Great care was taken to eliminate cases of tuberculous infection. No auxiliary treatment was given.

Sparteine Sulphate.—W. H. Zeigler (*Southern Medical Journal*, August, 1916) concludes from his experiments on various animals that sparteine is not a cardiac stimulant, but is a depressant to both the heart and the respiration. Death is due to failure of the respiration, aided by the action of the drug upon the heart muscle.

Therapeutic Action of the Soluble Salts of Emetine.—F. Fernandez Martinez (*Revista de Medicina y Cirugia Practicas*, July 21, 1916) recounts his experience with emetine in amebic dysentery and tropical hepatitis, and describes its action as efficacious, brilliant and specific in such cases. Its action in nonamebic diarrhea was unsatisfactory, but its hemostatic and antihemorrhagic power was well proven.

Vaccines in Acute Infections.—Ellis Bonime (*Medical Record*, August 12, 1916) brings out five important points in this regard, namely, a correct bacteriological diagnosis, the correct time of vaccine administration, correct interval between doses, prevention of the growth of microorganisms beyond the reach of antibodies, and the proper preparation of vaccines from growths of the causative organisms.

A Method of Treatment of Shell Shock.—E. T. C. Milligan (*Brit. Med. Jour.*, July 15, 1916), states that owing to the probable hysterical nature of this complex disturbance he has employed suggestion, while the patients were under the effects of chloroform until the stage just preceding involuntary struggling. The method yielded excellent results in the majority of cases, but at times it was necessary first to anesthetize the patient completely and resort to suggestion as he was recovering from its effects.

Action of Socalled Female Remedies on the Excised Uterus.—J. D. Pilcher, W. R. Delzell, and G. E. Burman (*Jour. A. M. A.*, August 12, 1916) made tests, using the excised, surviving uterus of a guineapig, a method which has given good results in the case of pituitary and other ecbolic drugs. The drugs employed were those commonly used in specialties and proprietary preparations advertised for the relief of menstrual and uterine troubles. Authentic specimens of the several drugs were obtained and identified by competent pharmacognosists. Fluidextracts and freshly prepared infusions were the preparations used. The drugs included black haw, blue cohosh, cramp bark, liferoot, Jamaica dogwood, pulsatilla, St. Mary's thistle, skullcap, unicorn root, valerian, wild yam, blessed thistle, false unicorn, lady's slipper, motherwort, and squaw vine. Blue cohosh was the only drug which caused stimulation and this threw the uterus into a state of tetanus. The others were either wholly devoid of all action or caused relaxation or complete cessation of contractions when used in considerable concentration. Only the fluid extracts were active in those cases where any activity was present, the infusions always being virtually inert. Excepting, possibly, blue cohosh, none of the drugs was found to be ecbolic or a uterine tonic, and it is very improbable that even this would be of value when taken internally, for the requisite concentration for the production of its effects could not be reached by this mode of administration. The use of these drugs is not only fruitless, but it is even harmful, since it perpetuates therapeutic fallacies.

Treatment of Diphtheria.—George E. Ebright (*California State Journal of Medicine*, August, 1916) advocates an initial dose of eight to ten thousand units, usually the latter, and the repetition of the dose every six, eight or twelve hours as occasion demands until there is evidence of effect upon the membrane. He feels that this procedure is best even in small children; that it hastens the termination of the infection; that by stopping the diphtheria intoxication as early as possible, complications are less frequent, and also that probably the length of time for the disappearance of the diphtheria bacilli is shortened; in other words, that the tendency for the development of carriers is less. In the discussion of this paper Cullen F. Welty remarked that people who have had their tonsils removed are not diphtheria carriers, and that the only way to get rid of a well established infection of the throat is to take out the tonsils.

Evacuation of the Uterus in Early Pregnancy with the Aid of Pituitrin.—J. L. Bubis (*American Journal of Obstetrics*, April, 1916) asserts that it is possible to empty the uterus in the early stages of pregnancy in a few minutes with the aid of pituitrin and a curette, with very little loss of blood and without shock or collapse even in the most severe cases. No hot irrigations are required to assist in the expulsion of the fetus or placenta, nor are any irrigations or packing employed after evacuation of the uterus. Preliminary packing of the cervix and vagina to induce softening of the cervix and excite uterine contractions is likewise usually not required. The injection of one c. c. of pituitrin is given after the cervix has been dilated, while the patient is under the anesthetic. Sometimes the curette is unnecessary, strong pains beginning within a few minutes and entirely expelling the uterine contents. Where the uterus is unable to evacuate itself, the curette is used to separate the adherent placenta from the uterine wall, a procedure which causes practically no bleeding, even if the placenta is removed piecemeal, owing to the firm, hard condition of the uterine wall due to the drug. The uterine cavity is wiped dry with gauze and swabbed with five per cent. iodine solution; it decreases in size as rapidly as its contents are removed. With this procedure Bubis has been able rapidly to empty many uteri in the fourth and fifth months of pregnancy in which a diagnosis of dead fetus had been made, but the cervix was closed.

Miscellany from Home and Foreign Journals

Movements of Foreign Bodies in the Brain.—Captain George Vilvandre and Captain J. D. Morgan (*Archives of Radiology and Electrotherapy*, June, 1916) report two cases with x ray photographs showing how a bullet changes its position in the brain. Beside shifting backward, the bullets rotated. The fact that damaged brain tissue is fragile and because of the patient's lying in one position for days at a time account for this migration.

Cultivation of the Organisms of Variola, Vaccinia, and Varicella.—Horace Greeley (*Medical Record*, August 12, 1916) describes the discovery and cultivation of small bipolar bacilli from the pustules of all three diseases which are actively motile, form spores, and are encapsulated. Primary cultures stain with difficulty, but full development brings easy staining power. The Gram test varies with the age of the organism, although spores and polar bodies are always positive. Agglutination tests were unsatisfactory, as the vaccinia organism was clumped more markedly by variola serum than the variola organism itself. The varicella germ was irregularly affected, but strangely was uninfluenced by the varicella serum.

An Entericlike Fever.—Albert J. Chalmers and Norman Macdonald (*Lancet*, July 22, 1916) have encountered several cases in the Sudan in which the symptoms were closely similar to those of typhoid fever, differing chiefly in the absence of enlargement of the spleen, less severe toxic symptoms, constipation and no mortality. From the stools of several of these cases an organism was cultivated which was neither *B. typhosus*, nor one of the paratyphoid bacilli. Its cultural characteristics are detailed in full, for it seemed to be an organism belonging to the *entericus* group which bridged the gap between *B. typhosus* and *B. coli*. It was found to give some group agglutination with sera from typhoid and paratyphoid and was well agglutinated by sera from the cases from which it was isolated.

Albuminuria Following Administration of Hexamethylenamine.—O. Leyton (*Lancet*, July 22, 1916).—A man thirty-nine years old was first seen nine years ago and, although then in apparently perfect health, his urine was found to contain granular casts and red blood cells, and to boil solid with albumin. The albumin consisted of serum albumin and serum globulin. Careful examination failed to reveal any evidence of renal disease or cardiac involvement, but it was found that he had been taking large amounts of hexamethylenamine and it was thought that the liberation of formaldehyde might have produced a permanent damage to the kidneys. The drug was being taken to relieve a colon bacilluria. He was seen again recently, nine years after his first visit, and the condition were found to be about the same as before and his health and strength were apparently still quite normal. The only change was the development of very slight evidences of some myocardial impairment. Following the second examination he underwent a surgical operation, from which he recovered normally.

Syphilis of the Bladder.—James Pedersen (*Medical Record*, August 5, 1916) insists that a diagnosis of bladder syphilis cannot be made in any stage of the disease by cystoscopy alone. It requires the corraboration of at least one essential such as history, Wassermann reaction or syphilitic signs elsewhere in the patient, or the therapeutic test. Although the condition is frequently overlooked, it presents a uniformly good prognosis when recognized and properly treated.

Cardiac Symptoms Following Dysentery.—E. B. Gunson (*Lancet*, July 22, 1916) states that in a group of sixty-five cases of dysentery, including both the amebic and bacillary forms, there were three deaths. In each of the three fatal cases there were serious symptoms of embarrassment, including dilatation of the heart toward the end. In seventeen per cent. of the cases which recovered, evidences of circulatory deficiency were also present, such as dyspnea, palpitation, vertigo, pericardial pain, and a feeling of exhaustion. These symptoms on the part of the heart lasted beyond the third week of convalescence.

The Circumpenile Muscle: Some Observations on the Anatomy of Phimoses.—Goeffrey Jefferson (*Surgery, Gynecology, and Obstetrics*, August, 1916), in connection with this subject, summarizes as follows: An examination of ten prepuces removed at circumcision and one entire penis and scrotum (fetal) confirms the existence of abundant unstriped muscle fibre beneath the skin of the penis. These are prolongations of the dartos sheet and form the circumpenile muscle. The fibres of this muscle possess the power of altering the preputial orifice to a certain extent, and hence a consideration of the latent powers of the muscle in causing varying degrees of phimosis is important.

Abdominal Pregnancy.—Frederick J. McCann (*Lancet*, July 15, 1916) records an interesting case of this rare condition in considerable detail. All of the evidence obtained during a laparotomy pointed to the probability of the condition having been primary in the abdomen. The pregnancy went to full term without causing the mother any distress and it was only diagnosed after the escape of a large amount of amniotic fluid from the vagina followed by a cessation in the further progress of labor. Upon operation a full term fetus, recently dead, was found lying free in the abdominal cavity but separated from the intestines by a thin amniotic sac which enclosed it and prevented the formation of intestinal adhesions. The placenta was normally formed and attached to the posterior aspect of the body of the uterus. It is suggested that the ovum found lodgement immediately after extrusion and fertilization at that point of the uterus upon which it would naturally fall when expelled from the ovary. There was certainly no evidence to believe that the pregnancy had originally been tubal and had become abdominal only after rupture of the tube.

Rupture of All Extensor Tendons of the Fingers from Gonococcal Tendovaginitis.—Eduard Melchior (*Berlin. klin. Woch.*, February 7, 1916) describes the case of a woman in which rupture of all the extensor tendons of the fingers of the left hand had occurred spontaneously. Only that of the thumb remained intact. Over the dorsum of the wrist was a swelling and a small, superficial ulcer. Culture of the thick creamy pus from the interior of the swelling yielded a pure growth of gonococci and the same organisms were isolated from the urethra and cervix. The initial swelling at the wrist had begun in association with a polyarthritis apparently also of a gonococcal nature. The condition was treated surgically.

Evacuating Patients from the Serbian National Military Hospital.—W. A. Jolley (*Military Surgeon*, August, 1916) notes that their hospital was practically an evacuation hospital; the patients being taken to Austria on hospital ships as rapidly as conditions permitted. It is hard to realize the work required to prepare 400 men for transportation. The order would be received to furnish 100 men, who could walk a little, or, in other words, handle themselves, 100 men who could ride sitting up, and 200 recumbent cases. This order would often come in the midst of other work, which would have to be dropped to get the men ready for shipment, and then they would often wait for several hours until they could be taken. One may read of train loads of wounded, but one cannot appreciate the amount of labor required in the handling of these men in addition to the feeding and surgical care involved.

Complications and Sequelæ of Operations for Inguinal Hernia.—Lincoln Davis (*Jour. A. M. A.*, August 12, 1916) has collected and analyzed fifteen hundred consecutive cases operated in for the relief of inguinal hernia. The cases were operated in by seventy-five different surgeons, including the members of the resident house staff. No cases of strangulated hernia were included. The ages of the individuals varied from ten months to seventy-seven years, the greatest number falling between the ages of twenty and thirty. There were 1,388 males and 112 females and in 1,244 cases the hernia was unilateral. Varying technic was employed and in many cases other operations were performed at the same time as that for the hernia, nevertheless the total mortality was only half of one per cent., and of the eight deaths two were not due to the hernia or to the operation. There were nonfatal postoperative complications in 438 cases, many of which were trivial. Some sepsis occurred in the wounds in 158 cases, but was slight in most. Respiratory complications were common, occurring in 138 cases, and included pneumonia, bronchitis, cough, pulmonary infarct, etc. One half of the total number of cases were followed up one year after operation. Of these seventy-six per cent were certainly entirely cured and many others were cured of their hernia but had some minor complaint associated with the previous operation, such as local anesthesia or pain in the wound. In only three and seven tenths per cent. of the total number of cases operated in were there definite recurrences.

The Cardiac Disabilities of Soldiers.—John Parkinson (*Lancet*, July 22, 1916) has made observations on ninety consecutive cases sent for treatment on account of cardiac symptoms following exertion, and comes to the conclusion that this is not a specific form of heart disease and does not merit a special name. In none of the cases were there any of the physical signs indicative of cardiac disease and the disability was always unmasked solely by the exertion. In nearly half of the cases there was a history of similar disability during civil life. The condition occurred following acute rheumatism, dysentery, and influenza; in men over forty years old as a result of some myocardial change; in association with some functional nervous disorder such as palpitation; and in cases endowed with a limited cardiac efficiency under normal conditions of life and whose heart did not respond to training. The symptoms complained of in these individuals could be reproduced by making them climb twenty-five to fifty steps, and the functional efficiency of the heart could thus be tested. The increase in the rate of the heart after exertion was found to bear no relation to the severity of the functional deficiency, and could not be employed as an index of this condition. Even in the absence of abnormal physical signs referable to the heart, such men were seldom fit for active medical service.

Concussion of the Nerve Centres Due to Explosions.—Jean Lépine (*Bulletin de l'Académie de médecine*, July 4, 1916) points out, from observation of over 1,500 cases of severe concussion, that, in contradiction to views held at the beginning of the war, concussion from shell explosions, manifested in sudden mental confusion with persistent apathy and headache, and at times deafness and dumbness, is not simply related to emotion or a neuropathic or hysteric state, but is associated with organic changes. The explosion exerts violent pressure on the surface of the body, especially the relatively soft abdomen—many complaining of abdominal pain as though a blow had been received there—causing increased pressure in the internal vessels, in particular those of the brain and cord, which are enclosed in an unyielding bony casing. The vessels thus tend to dilate and elongate, sometimes rupturing. The cerebrospinal fluid is often bloody for a few days, and occasionally hemoptysis and vesical hemorrhage are noted. The retinal vessels show a sinuous, dilated condition for some days after the injury. Immediately after the latter the heart beats feebly, rapidly, and irregularly—a condition unrelated to psychic shock, since it is noted in unconscious subjects who did not hear the shell coming. Brain congestion sometimes persists weeks or months, and may even result in a complete paralytic syndrome. Permanent low blood pressure, with weak heart action and the appearance of a strained heart, may also follow. Stretching of the perivascular sympathetic fibres may be a factor in these disturbances; inequality of the pupils and vasomotor disorders are frequent. In one instance a suboccipital herpes zoster appeared a week after the concussion. Concussion of the labyrinth, as a special phenomenon, must of course be differentiated from the central concussion just discussed.

The Indications for and Results of Cerebral and Cerebellar Decompression in Acute and Chronic Brain Disease. — Charles A. Elsberg (*Surgery, Gynecology, and Obstetrics,* August, 1916) holds the view that conservation is indicated in fractures of the skull and that there must be definite signs of brain lesion or symptoms of increasing intracranial pressure, before surgical interference is instituted. Excluding patients with depressed fractures or with large meningeal or subdural hemorrhages, Elsberg has collected from his records sixty cases of skull fracture that either were not operated in or in which a decompressive operation had been performed. He has excluded all those with gross lesions, whether depression of bone, laceration of the longitudinal or transverse sinus, and the like; although in every patient who is operated upon, except where the only lesion is an extradural hemorrhage, a decompressive opening should be left after the cause of the increased pressure has been removed.

Of the sixty cases of fractured skull, twenty-four or forty per cent. recovered without operative interference, although many required most careful watching and in some he was in doubt for many hours as to the need of decompression. Fourteen, or twenty-three per cent., were moribund when admitted to the hospital and their condition never improved sufficiently to allow of an operation, even without anesthesia. Twenty-two patients were operated upon and a unilateral or bilateral subtemporal decompression was performed. Seventeen patients recovered and five died. The deaths in every instance were due to extensive and hopeless laceration of the brain. In a number of the patients, extensive collections of blood were washed out from under the dura.

Bone and Joint Disease in Relation to Typhoid Fever.—John B. Murphy (*Surgery, Gynecology, and Obstetrics,* August, 1916) is of the opinion that joint destruction in typhoid arthritis is due to the same etiological factors as in other types of acute virulent arthritides, namely, a, the interarticular pressure produced by the products of infection, pus, etc., under tension hastens the destruction and absorption of tissue; b, interarticular pressure, due to involuntary muscle contraction, favors destruction and absorption of the cartilage and bone ends when infection is present; c, added to the foregoing factors we have the biotic and toxic destructive effects of the invading microorganism. All of these should be relieved at their earliest moment of manifestation. Whenever a joint is involved, as for instance, the hip or knee, a Buck's extension should be at once applied. It must be applied with greater care and watched more carefully for its pressure effects than other types of arthritis. Otherwise, dermatitis, pressure necrosis, etc., occur. When the hip is involved the limbs should be dressed in double abduction, because then luxation cannot occur. The tension from the products of infection, when effusion or swelling in the joint are great, can be relieved best by, 1, aspiration, which may be repeated frequently if tension recurs; 2, by injection and lavage of the joint with a one to 1,000 or a one to 500 solution of the hypochlorite of calcium, with immediate suture of the soft parts. Drainage should never be inserted, as this would favor or rather insure subsequent synechiæ or ankylosis. When the knee is involved great care should be taken to avoid hyperextension; that is, a few degrees of flexion should be maintained and frequent changes of position resorted to. If the joint infection manifests itself after the acute symptoms of typhoid have subsided and the patient is in the convalescent stage of the disease, vaccines of the autosensitized type should be resorted to. In the knee and hip lesions a cast should never be applied, as that favors ankylosis. In the ankle, the limb should be maintained in dorsal hyperflexion, which can best be accomplished by a cast. Passive motion, however, should be resorted to every day in order to avoid the tendency to ankylosis, which is always associated with a cast in these cases. When ankylosis has once developed, arthroplasty should be resorted to in about a year after the bony fixation has taken place. It never should be an early procedure, as latent viable foci of typhoid bacilli may be present. These produce an infection of the wound and militate against a good result. The simple opening of the hip or knee with lavage with the calcium hypochlorite solution, or opening and lavage with the phenol solution with immediate closure, not infrequently entirely cures the joint lesion in typhoid arthritis, as it does in the streptococcus arthritis of scarlatina, where this proceeding applied early gives the best results.

Detection of Disturbances of Equilibration and Orientation in Cases of Cranial Traumatism.—Cestan, Descomps, and Sauvage (*Bulletin de l'Académie de médecine,* July 4, 1916) have found that in many cases of cranial injury, whether intracranial exploration has or has not been done, and whether the injury has been produced directly or through violent atmospheric commotion, disturbances of orientation and equilibration constitute the only immediately discernible trace of a previous concussion of the brain. They describe an amplified form of the Babinski-Weill procedure for the detection of slight disturbances of this nature. The subject, standing in a large room or hall, is asked carefully to note the position of some object at some distance in front of him, then to make eight steps toward it with the eyes closed, next eight steps backward, and so on five to ten times. The usual abnormal result is a deviation such that a star-shaped figure is produced; less often a zigzag or hooked progression is noted, and rarely a curved progression. The authors adds to this procedure two identical tests, the first executed after the subject has made a complete turn on his heels, clockwise, with the eyes still closed, and the second, after he has made another complete turn, counterclockwise. Deviations from the straight line in one or more of the three tests are not considered abnormal, except under the following conditions: 1. where there is star-shaped progression in the same direction as the complete turn just executed, provided the total deviation in the six to and fro movements exceeds 30°: more particularly, 2, where the starlike deviation is always in the same direction, whatever the direction of the preceding complete turn, and, 3. where, after little or no deviation in the first test, a complete turn results in progression in a lateral direction.

Proceedings of National and Local Societies

AMERICAN PEDIATRIC SOCIETY.

Twenty-eighth Annual Meeting, Washington, D. C., May 9 to 11, 1916.

The President, Dr. Rowland Godfrey Freeman, of New York, in the Chair.

President's Address.—Dr. Rowland Godfrey Freeman, of New York, addressed the society on the subject of fresh air, by which he meant cool, dry, moving, out-of-doors air. This he considered an agent of wonderful power, its value being due not so much to the presence of oxygen and the absence of carbon dioxide as to the fact that it allows the body to control its moisture and temperature.

Recent Progress in the Physiological Action of Atmospheric Conditions.—Professor Frederick S. Lee, of New York, spoke by invitation on this subject, detailing some recent experiments in the Physiological Laboratory of the Columbia University School of Medicine that had resulted in bringing about a change in regard to the views concerning the physiological action of atmospheric conditions. He stated that when a certain external temperature is fairly comfortable, an elevation of it, especially when accompanied by humidity, is deleterious, and the more so when the air is stagnant.

Some Studies on the Mode of Infection in Pyelitis of Infancy.—Dr. Richard W. Smith, of Boston, spoke of the two conflicting theories regarding the mode of infection of the kidney in this condition, by the ascending and by the descending route, and said that aside from the greater frequency of pyelitis in female babies, there was no experimental or clinical evidence in support of the ascending route theory; while the descending, or hematogenous, route theory was supported by the evidence that the colon bacillus may enter from the gastrointestinal tract, and, in females, from the genital organs into the blood, and will be excreted by the kidney, causing inflammation at the pelvis of the kidney.

Dr. B. K. Rachford, of Cincinnati, asked why this infection was more common in females than in males.

Doctor Smith, in answer to Doctor Rachford, said that the reason was that in the female the urethra is shorter, making the possibility of infection greater.

Dr. Henry F. Helmholz, of Evanston, Ill., referred to some experiments in animals in which he was able, in three out of twelve cases, to show by means of the x ray that there was a reflux from the bladder into the ureter.

The next paper was one by Dr. Alfred F. Hess, of New York, on "Diet and Growth in Infantile Scurvy." (An abstract of this paper, with the full discussion thereon, has already appeared in the New York Medical Journal, June 24, 1916, page 1230.)

Sarcoma of the Kidney Treated by the X Ray.—Dr. Alfred Friedlander, of Cincinnati, described this case, which was inoperable, and said that the x ray had at first produced a decided shrinkage in the tumor and an increase in the weight and general well-being of the patient; but that later, the tumor had again increased greatly in size. The child had afterward succumbed to an intercurrent attack of measles.

A Brief Report of Sixty Blood Examinations with a Review of the Recent Literature of the Blood in Infants.—Dr. H. M. McClanahan and Dr. A. A. Johnson, of Omaha, presented this report of work, which was limited to the relative percentages of the white cells. The blood was taken without regard to the time of feeding. Sixty-eight infants, eighteen of whom were inmates of the Child Saving Institution, were examined for three weeks before the tests were made. All were between three weeks and two months of age. The results showed marked variation in the blood count.

Dr. Henry L. Shaw, of Albany, spoke of the great difficulty in establishing an average of white cells, on account of the fact that they vary a good deal and because of differences in classification. He considered it more accurate to give the maximum and minimum count for a certain age than to give a percentage.

Dr. Julius P. Sedgwick, of Minneapolis, had found it difficult to obtain normal counts. He stated that some charts made by a student in pediatrics at the University of Minneapolis in the case of 135 newborn infants confirmed the findings of Doctor McClanahan.

Dr. David M. Cowie, of Ann Arbor, said that the results of a similar experiment made by himself had shown the same curve as that exhibited. On the fourteenth day the red cells had almost entirely disappeared from the blood, and they did not reappear in the embryonal type.

The Creatin and Creatinine Content of the Blood in Children.—Dr. Borden Veeder and Dr. Meredith Johnson, of St. Louis, had made determinations of the creatin-creatinine content of the blood in seventy-five children, and had found that the figure for normal children varied between one and two milligrams per 100 c. c., being somewhat higher than that for adults. The figure for creatin in the normal child averaged from four to six milligrams per 100 c. c., or considerably less than in the adult. No specific retention was observed. Comparisons with the total nonprotein nitrogen of the blood had been made in every case. The authors found that in nephritis there was a tendency for an increased retention of the nonprotein nitrogen without a definite increase in the creatinine. Such factors as age, sex, and starvation, were without effect on the creatin-creatinine content. No definite relationship was found between the creatin-creatinine of the urine and that of the blood.

The Hospital Care of Premature Infants.—Dr L. E. LaFetra, of New York, stated that he had gone through the records of the last 200 cases at Bellevue and had found thirty premature infants that had been saved. One hundred and eighteen had died during the first three days, and thirty-six per cent. of those that had lived beyond this time were

saved. Doctor La Fetra said that in treating these babies, the conditions of intrauterine life should be simulated as far as possible. While he considered the incubator designed by Dr. E. A. Cragin the best, he did not consider it usually a good thing to use an incubator. He preferred a small room that could be kept at the proper temperature, and said that such a room was also of advantage in managing feeble infants that were not premature. Breast milk mixed with whey should be given, and the food put into the infant's mouth, and often even into its stomach.

Doctor Veeder stated that at the Children's Hospital in St. Louis they had a similar room, in which they were able to maintain the temperature at 85° F. The children were left undressed on the bed. From 120 to 150 calories had been found necessary in order to make these infants gain. After they had been in this room for about two months, they had to be placed in the ordinary ward before again beginning to increase in weight.

Doctor SEDGWICK said that he had had considerable success with the four-hour feeding of premature infants, although Doctor LaFetra had not.

Doctor LAFETRA asked to hear the technic of these four-hour feedings, and said that he would be glad to give them a trial. He had not previously succeeded in getting in enough food by this means in the twenty-four hours.

Doctor SEDGWICK stated that they used breast milk, starting with ten or fifteen c. c. five times a day, and increasing the amount as rapidly as possible up to the quantity necessary to produce from 120 to 150 calories.

Dr. B. RAYMOND HOOBLER, of Detroit, stated that last winter, with a four-pound premature child, he had been able to maintain the room at the temperature considered necessary by Doctor LaFetra with the humidity in proper proportion.

Further Experience with Homogenized Olive Oil Mixtures.—Dr. MAYNARD LADD, of Boston, described a method of substituting olive oil for cows' fat in milk modifications, in order to get rid of the fatty acids, which are considered to be the cause of indigestion in certain cases. By this method he could obtain minute and permanent emulsions of the fats. In a series of thirty-seven cases, which had been unsuccessfully fed during an average of 6.3 months each, with a gain of only five ounces a month, successful results were obtained by the use of the Caulin homogenizing machine. When this same set of children were fed on the mixtures thus prepared, the rate of gain over a period of 4.7 months was increased to 18.15 ounces a month, with a corresponding improvement in the general condition of the patients.

A Method for Preparing Synthetic Milk for Studies of Infant Metabolism.—Dr. HENRY I. BOWDITCH and Dr. ALFRED W. BOSWORTH, of Boston, described in this paper a method consisting of four steps: The preparation of isolated food materials for use in making milk; the reassembling of these materials to give a mixture of the desired percentage composition; the emulsification of the fat and the solid or insoluble constituents entering into the composition of the food; and the pasteurization or sterilization of the food after it had been made. This synthetic milk strongly resembled the natural food in appearance.

A Study of the Topography of the Pulmonary Lobes and Fissures with Special Reference to Thoracentesis.—Dr. J. C. GITTINGS, Dr. GEORGE FETTEROLF, and Dr. A. GRAEME MITCHELL, of Philadelphia, as the result of this study, had concluded that the lowest safe point for doing thoracentesis in infants was the sixth or seventh interspace, mid-thoracic line. The best results were obtained in the fifth or sixth interspace, mid-thoracic line. Apparently the shape of the chest in infancy had nothing to do with the shape of the lungs or the position of the fissures.

Deformities of the Costochondral Junctions in Rickets.—Dr. EDWARDS A. PARK, of Baltimore, said that rickets might be extremely advanced in a rib, and yet produce no deformity at the costochondral junction. When this occurred, the cartilage became separated from the end of the rib, articulating only with the side of the rib on one aspect. In the angle between the two there would be found a wedge-shaped mass of periostum. The end of the shaft would take a position internal to the cartilage. He said that no growth would take place at the deformed costochondral junction so long as the rachitic process was at its height.

Report of the Committee on Vaginitis.—The Committee, consisting of Dr. J. C. GITTINGS, Dr. S. McC. HAMILL, Dr. C. A. FIFE, and Dr. H. C. CARPENTER, of Philadelphia, made the following recommendations, which were unanimously adopted by the Society:

1. That the American Pediatric Society address a letter to Health Officers, containing the following recommendations:

A. That cities be required to provide adequate hospital and dispensary facilities for the care and treatment of children having vaginitis. B. That matrons be placed in charge of the girls' toilet rooms in public schools. C. That toilet seats embodying the principle of the U shape be used in all schools, and that the toilets be of proper height for different ages. D. That city and State laboratories be empowered and equipped to make bacteriological examinations for physicians when patients cannot afford to pay a private laboratory fee. E. That educational literature on the suject of vaginitis be prepared and distributed to mothers through the medium of physicians, hospitals, dispensaries, health centres, and municipal and visiting nurses. F. That asylums for children and day nurseries be licensed, and that the license be not granted unless, first, the institution has adequate facilities for the recognition of gonococcus vaginitis; and, second, the institution excludes children having this disease, if they cannot be properly isolated.

2. That the American Pediatric Society address a special letter to hospitals which care for children, containing the following recommendations:

A. That separate wards be maintained for the treatment of children with vaginitis who are also suffering from other diseases. B. That microscopic examinations of smears be made before admission to the general wards of the hospital. In securing

material for the smears, extreme care should be taken to observe rigid aseptic precautions. C. That observation wards be provided. D. That individual syringes, bedpans, catheters, clinical thermometers, thermometer lubricant, wash basins, soap, powder, wash cloths, and towels be provided. E. That single service diapers be used (at least, for girls); or, that diapers be sterilized in an autoclave at fifteen pounds pressure for five minutes. F. That nurses be required to make a daily inspection of the vulva of each child at the time of bathing, and to report immediately the presence of the slightest suggestion of a vaginal discharge. G. That low toilets be provided and equipped with seats embodying the principle of the U shape. H. That, for routine purposes, the spray be used in place of tub baths for the bathing of young girls, and that older girls be sponged in bed. I. That nurses receive special instruction as to the nature of vaginitis, the ease with which it is transmitted, the methods of preventing its spread, and the necessity for rigid aseptic surgical technic in its handling and treatment. J. That a dispensary with special facilities for the treatment of gonococcus vaginitis be provided. K. That nursing care and supervision be given in the home. L. That mothers be instructed as to the dangers of vaginitis, the manner in which it is transmitted, the best method of protecting other children, and the necessity of prolonged observation. M. That all cases of vaginitis under observation be voluntarily reported to the local Health Officer in States or cities where no legal requirements are in force.

Certain Phases of the Vulvovaginitis Problem.—Dr. B. K. Rachford, of Cincinnati, considered bacteriological tests for this disease as being far from wholly satisfactory, and likewise the means now in use for its prevention and cure. He said that the manner in which gonococcus vaginitis is spread in the child and in the adult could not be more unlike, if they were entirely different diseases, the former nearly always disappearing at puberty, and very rarely having any complications or sequelæ. While the course of the disease could be materially shortened by local treatment, this treatment, if overdone, might bring about pernicious habits.

Some Early Symptoms Suggestive of Protein Sensitization in Infancy.—Dr. B. R. Hoobler, of Detroit, stated that the reaction following the absorption of a sufficient amount of unaltered foreign protein, known as protein sensitization, is not of an explosive character, as in acute anaphylaxis, but is suppressed. He divided the symptoms into five groups, relating, respectively, to the skin, the upper respiratory tract, the lower respiratory tract, the digestive system, and the nervous mechanism, and said that these symptoms may come and go with great rapidity, different ones appearing at different times in the same individual. They gradually increase in severity and variety, appear more frequently, and remain longer. Many of them are also symptoms of other common diseases. Doctor Hoobler considered it important that the condition be recognized early, so as to prevent, by desensitization, its later manifestations.

(*To be concluded.*)

AMERICAN GYNECOLOGICAL SOCIETY.

Forty-first Annual Meeting, Held at Washington, D. C., May 9, 10, and 11, 1916.

The President, Dr. J. Wesley Bovee, of Washington, D. C., in the Chair.

(*Concluded from page 382.*)

The Constitutional Factor in Gynecology and Obstetrics.—Dr. Charles P. Noble, of Philadelphia, presented these conclusions: 1. The theory of environmental, constitutional hypoplasia or arrested development from unfavorable environment, operating at any period from the preconceptional state of dual life in the ovary and testis, to that of the youthful period in ontogeny, which was presented to the profession as a medical hypothesis in 1908, and which the writer believed to be proved upon human clinical and pathological evidence, was now shown to be equally supported by the clinical and the pathological facts of antenatal pathology and by the facts of comparative pathology, and to be demonstrated by the facts of experimental teratology. 2. The wisdom of the fathers of medicine, as expressed in their discriminating analysis of the facts of the hereditary nature of the diatheses or dyscrasias, together with the theory of environmental hypoplasia, constituted the law of devolution in its relation to medicine. 3. In order to obtain a comprehensive understanding of the practice of medicine, it was necessary to reject such of the teachings of Virchow and of his followers as were fallacious, and to combine the clinical wisdom of the fathers of medicine, from Hippocrates down, with the known facts of experimental medicine and their correct interpretation, and thus to arrive at the true point of view from which to study and to deal with the clinical problems which were the concern of practitioners of medicine and of each of its specialties. 4. The constitutional factor in gynecology and obstetrics, as was equally true of the other departments of medicine, was the chief element in the clinical problems which confronted the practitioner in dealing with disease and with atypical organs and tissues and their functions. 5. The recognition, comprehension, and employment of the foregoing principles would greatly enlarge the powers of the practitioner of medicine in diagnosis, prognosis, and in therapeutics, and would enable him to avoid many common, if not habitual, errors, and positively to substitute general nutritional and developmental measures for the local measures currently employed, and thus effect a cure, instead of mere amelioration of his patient's condition when this was due to environmental arrest. Further, it would enable him to give scientifically based advice as to methods of living when the biological type of the patient was recognized; to promote the development of environmentally arrested patients, and to enable them to maintain their health by living within their particular potential or capacity to produce energy, instead of attempting to live physiologically as typical individuals, which would, however, cause disease in the arrested or hereditary and environmental devolutes. 6. There remained unsolved two problems: 1. The process or mechanism whereby atypical morphology and function of

environmental origin in ascendants became, at least, hereditary in descendants. Apparently its solution would be found in the facts of the maleficent consequences of urbanization in human stocks, which escaped extermination by degeneration and disease, and the variations and adjustments which ensued, whereby acquired immunity was attained; and similar facts concerning the consequence of the long continuance over generations of other unfavorable environment, such as insufficient nourishment, malaria, the hookworm, and food deprived of some element necessary to nutrition, or so mistreated as to be relatively poisonous. It might become demonstrated by subjecting shortlived animals to definite, unfavorable environment, for twenty or more generations, and observing and correlating the facts thus obtained. Facts from biology as to species of animals and plants subjected for generations to inimicable environment would also aid in the solution. 2. The eradication of degeneracy and its prevention would probably find solution in the development of euthenics and in the segregation or sterilization of subjects manifesting marked degrees of degeneracy, more especially of the hereditary types.

Precancerous Changes in the Uterus.—Dr. William S. Stone, of New York, pointed out the evolutionary character of the different types of cancer of the uterus as beginning in definite benign lesions, such as erosions, leucoplakia, and glandular hyperplasia, which showed variable quantities and qualities of epithelial overgrowth and metaplasia that might differ litle from the regenerative activity observed in the benign lesions, or after a longer or shorter time might show atypical features that were differentiated with difficulty from the alterations they knew typified malignant neoplasm. To such pathological changes the speaker thought the term, precancerous, might be appropriately applied, as they appeared to represent changes that were neither cancerous nor noncancerous, but were in the stage of becoming cancerous. Their relation to the development of a cancerous growth was shown by the fact that their morphological features included, in different combinations of quantity and quality, the numerous histological criteria upon which the diagnosis of a fully established cancer was made, lacking only in some instances the features of destructive activity and purpose. The strongest support of this conception was derived from the reproductions of types seen in the different stages of their progress. In the author's material, for example, he found the atypical features of a healing erosion determined by the original type of the lesion—simple, papillary, follicular, and the atypical types again reproduced in the different types of fully established uterine cancer. There were atypical erosions which were prototypes of either an epidermoid cancer or a papillary adenocarcinoma. There were leucoplakias which were prototypes of adult acanthomas. There were glandular hyperplasias which led to adenoma or adenocarcinoma. Finally, there were focal areas of leucoplakia, combined with adenomatous hyperplasia which might well furnish an origin for tumors designated as adenoacanthomas. In short, for each type of fully developed carcinoma there was a corresponding type of benign and intermediary change.

The literature had been critically reviewed, showing increasing evidence confirmatory of the sequence of benign lesions in the uterus and cancer, but the efforts to define their histogenetic relation had been limited to a few writers. More fully to verify the assumption that morphological features of intermediary stages existed, a closer cooperation between the clinician and the pathologist would be required. For the present, it was no argument against such an assumption that no tumor process was present or followed in a given case. The evidence in the literature was already sufficient to show that a fully established cancer might exist for a certain time without giving gross evidence of its presence, and numerous cases were recorded in which the curette had completely removed the lesion. There was no reason to assume that precancerous changes without treatment must always develop into malignant growths. Different types of fully established tumors had a different capacity to grow and destroy rapidly or slowly, and it did not seem reasonable to assume that a developing cancer had the same momentum that a fully established tumor possessed. In the study of beginning cancer of the uterus, several authors had directed attention to the fact that a certain type of early cancer might spread superficially over a wide area before showing marked invasive features, and it had occurred to the speaker that such a mode of growth might account in some measure for the extent of the process before it received the attention of the clinician. With the description of the speaker's cases there were sufficient clinical data to show the practical side of the problem, that the decision regarding the proper therapeutic procedure in such cases should be assumed by a competent clinician.

Painless Labor.—Dr. J. Clifton Edgar, of New York, pointed out that shock from the pain of labor in the highly civilized neurotic woman must be reckoned in general child bed mortality. Painless labor in these women was a life saving measure. The problem was the control of the pain in the first stage, the longest stage, often lasting a day or more. For the moment there was no ideal single method of painless labor. The only absolutely painless labor was one terminated by surgical means with complete anesthesia. Conditions would always arise, for example, in early rupture of the membranes, in which the necessity for painless labor would demand such surgical termination. The most satisfactory painless labor method of the moment combined opium and antispasmodics for the first stage, with possible vapor narcosis toward the end of this stage; vapor analgesia and anesthesia for the first and terminal parts of the second stage respectively. The narcosis aimed at should, until the perineal stage, be analgesic and not anesthetic in character, whether by drugs or vapor—a difficult or impossible object to attain unless they had had considerable experience.

In analgesic work, there was the tendency of the patient coming out from under the influence of the gas to suffer from the effects of shock owing to the acuteness of the suffering, or of anesthesia being produced with its dangers in the hands of the novice. To sum up, nitrous oxide-oxygen analgesia or "obstetric" ether or chloroform should be used for the

second stage, pushed to anesthesia for the perineal stage; possibly forceps delivery with vapor anesthesia to eliminate part of the second stage. Nitrous oxide-oxygen analgesia or anesthesia was superior to any other during labor because of its oxytoxic action. Eventually an established method of painless labor might be related to public health questions. Lessening or abolishing the pain of labor might in the future limit birth control and criminal abortion.

Letters to the Editors.

HUMAN CONTAGION OF POLIOMYELITIS DOUBTFUL.

Long Branch, N. J., *August 19, 1916.*

To the Editors:

Permit one who has been on the firing line for half a century respectfully to suggest to the strategists (laboratory workers) of medicine to search in the mouths and noses of healthy children and adults for the microorganism of poliomyelitis. History tells us that Sternberg (afterward surgeon general of our army) inoculated in 1880 a rabbit with his own saliva and thus discovered a micrococcus which later came to be recognized as the chief etiological factor in pneumonia. It is a well known fact that this organism is found in the respiratory passages of pneumonia patients and that it is *frequently found in large numbers in the mouths of perfectly healthy persons.* The microorganism resembles somewhat that of poliomyelitis in shape and arrangement in pairs, also in its being found in the respiratory tracts of the patient and in *the mouths of perfectly healthy persons,* who are now termed carriers; other resemblances are that secondary cases are rare in both diseases, and that no immunizing agent has been discovered for either one. That this view is warranted by the facts is evident from the only reliable report of human transmission on record, viz., Sawyer's article in the *American Journal of Tropical Diseases,* September, 1915. He traces in all his cases as the *possible paths* of infection, four healthy men, the fathers of the patients, only one of whom is known to have been in contact with the disease eighteen months previously. Further details must be omitted here for lack of space. The fact that Sawyer himself regards these fathers as *possible* factors is additional evidence of the far fetched character of this singular theory of chiefly healthy carriers, which is in direct contradiction to the fact that in all other infectious diseases the *patient* is the chief source of transmission. In view of the pathetically mysterious status of this question, I hope that active search may at once be made for the microorganism, and that it may be found present in many healthy persons, irrespective of their proximity to poliomyelitis cases, which like pneumonia may be found to develop only under favoring conditions that may be limitable.

Quarantine. Busily engrossed with the most urgent therapeutic problem of recent time, physicians have singularly permitted the adoption without protest of a drastic quarantine, which appears to be unwarranted in view of the *unproved transmission* from human to human. Dr. Simon Flexner, who has proved only transmission from humans to monkeys, warns against "undue concern regarding the danger of conveying the disease." He writes: "It appears that these carriers are not more numerous in this disease than in many other infections of more common origin."

That human contagion is not proved is evident from the writings of authorities, e. g., Frost stated in the recent conference of health officers that the evidence *points* strongly to human carriers—*if it is contagious,* a large number are immune; it must be spread largely by other than sick persons—*mostly adults. Against* that is the seasonal prevalence and I may add the incompatibility with *facts* in other infections.

The same authority wrote in the July 14th *Report of the U. S. Public Health Service:* "Statistics of 2,070 persons exposed to poliomyelitis by residence with patients, show that only fourteen (0.6 per cent.) developed the disease in its frank form. . . . The contagiousness must be very slight, less than one fifteenth that of scarlet fever. . . . It may be fairly definitely concluded that it must be slightly or rarely transmissible, since it develops in small proportion in persons associated with acute cases."

This is confirmed by the observations of the New York Health Department that "the number of secondary cases is *decidedly small"* and that they are "comparatively rare cases," and by the proved *fact* that in the Vermont as in most other epidemics, "the disease originated in many sparsely settled townships far from the main highways in families that had not been in communication with the outside world."

No wonder that Frost said, after citing many instances in proof, "many investigators seriously doubt or deny the transmissibility of the disease."

In view of the fact that poliomyelitis is rarely contracted from contact with an acute case and of the accepted idea that it is mostly spread by adults, exclusion quarantine should logically be enforced on adults rather than on children. Rigidly enforced, such a quarantine would stop all travel, with the result that public resentment would immediately terminate it.

Having so far as I know stood alone in strenuous opposition to drastic quarantine, it is gratifying that the Washington Conference of Health Officers announced yesterday that *municipal quarantine is unnecessary.* They may well have added "futile and unwarranted."

That it is just as unnecessary and will be just as futile to close the schools as a quarantine measure is clearly demonstrated by the fact that in Newark before the schools attended by 25,000 children were closed there had occurred eighty cases of poliomyelitis, while afterward the number increased to 247 to the end of the month, and in August the number was 636. It is probable that other school closings have proved equally ineffective. It is imperative, therefore, that this matter be carefully investigated before all the schools and universities are closed by the unreasoning panic. The "psychology of the crowd" is demonstrated by the fact that no such panic has ever been created, by the actual fact that 9,000 deaths occur in New York city every year, accounting for about 50,000 cases of pneumonia.

Is it not high time for calmer judgment? The "psychology of the crowd" demands judicial reasoning to allay unreasoning fear. Simon Baruch, M. D.

INFANTILE PARALYSIS: THE PRACTICAL AND THE FOOLISH IN PREVENTION AND TREATMENT.

Westport, N. Y., *August 17, 1916.*

To the Editors:

In a letter to the *New York Evening Post,* some weeks ago, I pointed out what might be done in the way of prevention and care generally in cases of infantile paralysis. Later, I published two communications in the New York Medical Journal, stating what I believed was the most intelligent treatment, preventive and curative probably, of the disease, available to every one. I have not ignored, nor do I now, the utility at times of quinine, which has shown itself in my experience as being useful in certain instances of infectious disease. On the other hand, I am convinced it is not so useful as salicylate of ammonium internally, and given at the same time, they have seemed to me to be prejudicial in their effects. The use of carbolated vaseline in the nares is useful and unobjectionable

As to injections of immunized blood serum—probably given by an expert and with every precaution as to careful preliminary examination of the donor—it is being tried with obvious good results. Its use is limited, because of the supply that is obtainable. Besides, it should not be used, in my judgment, by the ordinary practitioner when he first sees the patient, nor at a time previous to his being called, when the preventive measures, which I have insisted upon, might be used even by the inexperienced physician, with practically no risk in any way. If not sure preventives, they are surely the best that have hitherto been offered from every point of view.

I await anxiously the verdict of my colleagues everywhere—my testimony is that from a long and varied experience. Beverley Robinson, M. D.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Surgical Nursing and Technic. A Book for Nurses, Dressers, House Surgeons, etc. By CHARLES P. CHILDE, B. A., F. R. C. S., Eng., Lieutenant-Colonel, Royal Army Medical Corps (Territorial), Senior Surgeon, Royal Portsmouth Hospital, etc. New York: William Wood & Co., 1916. Pp. xv-229. (Price, $2.)

Carefully revised and under a new name, *Operative Nursing and Technic* appears in its second edition. The demand for another edition was well merited, for among surgical textbooks for nurses *Surgical Nursing and Technic* is unique. It should find a place in the equipment of every up to date nurse. In the first chapter the author discusses the desirable qualities of the surgical nurse from an original point of view and enters a plea for shorter hours and more adequate remuneration of the hospital nursing staff. Following a discussion of asepsis and antisepsis, the requisites of a surgical case are given in explicit detail. The preparation and care of surgical patients from their entrance to the hospital until dismissal, the duties of an operating theatre sister and nurse, the care, preparation, and sterilization of all surgical articles, the selection of instruments, and requirements for operations in surgical homes and private houses are fully explained, and, in conclusion, nursing in military hospitals.

Written to meet the special needs of English nurses and with phraseology occasionally unfamiliar to many American nurses, the book will be found none the less useful for their guidance.

Although addressed to the nursing profession, it is the author's hope that the contents of this book will be found useful to students and dressers, as well as junior members of the medical profession. Its pages contain "the kind of practical information regarding operation cases required of students and dressers, but it is necessarily expounded in more elementary form than if it had been intended primarily for the latter. It is possibly none the worse for being elementary and entirely practical. Also, without presuming to give instruction to such, house surgeons, on first taking office, and young surgeons may perhaps find some assistance from these pages in the marshaling of their facts and the organization of their operative work. Surgery and surgical nursing necessarily overlap in places, and though the nurse cannot aspire to be a surgeon, every surgeon should be a good surgical nurse."

Burdett's Hospitals and Charities, 1916. The Year Book of Philanthropy and Hospital Annual. Containing a Review of the Position and Requirements on the Management, Revenue and Cost of the Charities. An Exhaustive Record of Hospital Work for the year. It will also be Found to be the most Useful and Reliable Guide to British, American, and Colonial Hospitals and Asylums, Medical Schools and Colleges, Nursing and Convalescent Institutions, Consumption Sanatoria, Religious and Benevolent Institutions and Dispensaries. By Sir HENRY BURDETT, K. C. B., K. C. V. O., Author of Hospitals and Asylums of the World; Hospitals and the State; etc. Twenty-seventh Year. London: The Scientific Press, Ltd., 1916. Pp. xvi-1071.

This excellent and conscientiously edited work appears for the twenty-seventh year without evidence of abridgment or other drawback, despite the editor's plea that the price of pulp paper, and the effects of war upon not only printers and editors, but also on hospital superintendents and secretaries, have added enormously to his difficulties and responsibilities. Fully 6,000 institutions are dealt with in this book, which includes hospitals in the United States and Canada as well as in Great Britain, and the annual cost of producing it is stated to amount to over $50,000. Included this year are all the territorial hospitals with the name of the matron in each case. Next year, a list of convalescent camps is promised. The venerable editor announces that he will soon celebrate his seventieth birthday and renews his request that some properly equipped person come forward to take his place; such a person, we venture to state, will not be easy to find. A high tribute is paid to the voluntary system on which hospitals in Great Britain are based and a comparison is instituted between the sympathetic treatment accorded to patients therein, and the coldly scientific attitude said to exist toward the inmates of certain prominent German hospitals. The book continues to be indispensable to editors of all kinds of periodicals, and a large demand seems to exist among lawyers. It is no mere list of institutions, this work; the fifteen introductory chapters take up in excellent literary form all sorts of questions connected with hospitals, their construction, for example, maintenance, nursing, missions, special institutions for the blind and the deaf and dumb, etc.

The Diagnosis and Treatment of Heart Disease. Practical Points for Students and Practitioners. By E. M. BROCKBANK, M. D., F. R. C. P., Hon. Physician, Royal Infirmary, Manchester, Clinical Lecturer on Diseases of the Heart, Dean of Clinical Instruction, University of Manchester. Second Edition. With Illustrations. New York: Paul B. Hoeber, 1916. Pp. 120. (Price, $1.25.)

It is a pleasure to welcome a second edition of Doctor Brockbank's little work; it is still of pocket size, which is an important factor in its usefulness. Books of this kind are very apt to grow unwieldy as editions multiply. The student who masters this volume may consider himself fairly well equipped to handle most of the cardiac cases which come under his observation. The concluding chapter is an admirable one on treatment; it is fortunate that the heart responds to so many drugs, for it is possible to mitigate greatly and for a long period the anguish and anxiety of the patient who first learns of his cardiac disability.

Interclinical Notes

War Letters of an American Woman form a new series in the *Outlook*, which began in the issue for August 2d; news of the wounded and sick and of doings in the hospitals make up a large part of their most interesting contents.

* * *

In *Leslie's* for August 10th there is a picture of a group of Chicago "society women," who desire to accompany the Red Cross to war. Judging from the broad smiles on the ladies' faces, nursing in war is looked upon as somewhat of a lark by the *haute volée* of the lacustrine metropolis.

* * *

We are sorry to learn that the Poe portrait which appeared in the April number of the *Century* lacks certification; we thought that it looked very genuine. The pictures, including the cover of the August issue, are beautiful; there are some cool looking Alps in the frontispiece that we admire immensely.

* * *

The August *Scientific Monthly* managed to get in an editorial article on infantile paralysis. Dr. C. C. Little discusses the Relation of Heredity to Cancer in Man and Animals, and Professor Frank T. Carlton takes up a subject which seems likely to concern physicians for some time to come, viz., Essentials in the Study of Labor Organizations. Sir Ronald Ross and the Prevention of Malarial Fever, by Major General William C. Gorgas and Dr. Fielding H. Garrison, will be found to be of special interest to our readers.

* * *

In the *Outlook* for August 16th, an article on The Moon and the High Cost of Living, by Lewis Edwin Theiss, gives the astonishing information that the farmers of the United States in this twentieth century are a prey to old fashioned superstitions, and that the dark of the moon plays a large part in their calculations of crops to come. They plant cucumbers on June 21st, the longest day of the year, in order to have long cucumbers. The majority of farmers are so beset with fears and superstitions and so held in the bondage of custom and authority that they cannot take advantage of the opportunities that lie at their hands. The farmer does not think, he does not reason, he refuses to be exact, his mind is impervious to new and beneficial

ideas. Money is lost in enormous sums from superstitions which come down from the ancient Greeks. There seems to be no way of educating the farmers out of their settled ideas. Mr. Theiss's paper is a discouraging revelation; no doubt, if the truth was known, the man in the street has his own collection of hoodoos. No wonder it is difficult to make any scientific advance in matters which obviously concern the public health.

* * *

Where do these young and new writers get their power of characterization? In the *Century* for August Phyllis Bottome begins a three part story, The Dark Tower, in which the hero and heroine are real *tours de force*. On the other hand, Krujer Hobbs, by Marjory Morten; The Bomb, by Alice Woods, and The Veil, by Katharine Holland Brown, seem to us to be little else than episodical. Cricket, by Stacy Aumonier, revived certain memories. We have clean forgotten, however, where "long leg" stands, also the meaning of the question, "Who would come off for us?" The author says that the birds and the insects praised God in solemn unison. We remember perfectly what unison is, and it is not what birds and insects sing in.

Official News

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the United States Navy for the three weeks ending August 12, 1916:

Hawke, W. W., Assistant Surgeon. Commissioned from July 5, 1916.

Little, R. M., Assistant Surgeon, Medical Reserve Corps. Ordered to duty at the navy recruiting station, Peoria, Ill.

Plummer, R. W., Surgeon. Detached from the *Hancock* and ordered home to await orders.

Pryor, James, Surgeon. Detached from the Naval Hospital, Annapolis, and ordered home to await orders.

Rogers, W. J., Assistant Surgeon. Detached from the Marine Barracks, Pensacola, Fla.

Roddis, L. H., Assistant Surgeon. Detached from the *Elcano* and ordered to Canacao Hospital, P. I.

Shaw, Harry, Surgeon. Commissioned from April 28, 1915.

Strite, C. E., Passed Assistant. Detached from the Aeronautic Station, Pensacola, Fla., and ordered to the *Louisiana*.

Toulon, A. J., Passed Assistant Surgeon. Ordered to the Aeronautic Station, Pensacola, Fla.

Walton, D. C., Passed Assistant Surgeon. Detached from the Canacao Hospital and ordered to the *Wilmington*.

Watt, James, Assistant Surgeon. Commissioned from June 28, 1916.

Wilson, Talmadge, Assistant Surgeon. Detached from the *Wilmington* and ordered to the *Eleano*.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 16, 1916:

Applewhite, C. C., Assistant Epidermiologist. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation in Cumberland County.

Banks, Charles E., Senior Surgeon. Directed to report at bureau, Washington, D. C., August 17th, to participate in conference of State and territorial health authorities with the bureau relative to poliomyelitis.

Bruckmiller, F. W., Sanitary Bacteriologist. Directed to proceed to Cincinnati, Ohio, for duty in studies of industrial wastes.

Carter, H. R., Assistant Surgeon General. Granted one month's leave of absence from September 20, 1916.

Collins, R. H., Scientific Assistant. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation in Cumberland County.

Fricks, L. D., Surgeon. Directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

Harolson, M. F., Field Inspector. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation in Cumberland County.

Hasseltine, H. E., Passed Assistant Surgeon. Granted two days' leave of absence on account of sickness, July 24 and 25, 1916.

Jones, W. M., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

Lanza, A. J., Passed Assistant Surgeon. Directed to proceed to Billings, Mont., to advise the State and local authorities relative to poliomyelitis.

Lavinder, C. H., Surgeon. Directed to report at bureau, Washington, D. C., for conference relative to poliomyelitis.

Le Prince, J. A. A., Sanitary Engineer. Directed to proceed to Providence, R. I., for survey of malarial conditions.

Paine, Liston, Assistant Surgeon. Directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

Rucker, W. C., Assistant Surgeon General. Directed to proceed to Baltimore, Md., for conference relative to poliomyelitis.

Stewart, G. McC., Acting Assistant Surgeon. Directed to report to Passed Assistant Surgeon F. Simpson for duty in plague suppressing measures in New Orleans, La.

White, H. F., Assistant Surgeon. Granted fourteen days' leave of absence from August 10, 1916.

White, M. J., Surgeon. Directed to proceed to Liberty and other places in Clay County, Mo., to supervise studies of rural sanitation.

Ziegler, M. V., Assistant Epidemiologist. Directed to proceed to Toledo, Ill., for duty in studies of rural sanitation in Cumberland County.

Births, Marriages, and Deaths

Born.

Krantz.—In Laurel, Md., on Tuesday, August 8th, to Dr. and Mrs. Herman Krantz, a son.

Married.

Potter-Tripp.—In New Bedford, Mass., on Monday, August 7th, Dr. Leslie F. Potter and Miss S. S. Tripp.

Died.

Brown.—In Benton, Ill., on Wednesday, August 9th, Dr. John P. Brown, aged seventy-three years.

Browne.—In Shenandoah, Pa., on Friday, August 11th, Dr. Alexander Browne, aged seventy-three years.

Dorfman.—In New York, on Thursday, August 10th, Dr. Waldemar Dorfman, aged sixty-two years.

Dunn.—In Henderson, Ky., on Thursday, August 10th, Dr. Miles C. Dunn.

Eager.—In Naples, Italy, on Thursday, August 17th, Dr. John M. Eager, of Philadelphia, Pa., aged fifty-two years.

Gollwitzer.—In Pittsburgh, Pa., on Thursday, August 10th, Dr. Adam J. Gollwitzer, aged seventy-five years.

Hayes.—In South Yarmouth, Mass., on Sunday, August 13th, Dr. Wentworth L. Hayes, aged thirty-nine years.

Johnson.—In Chicago Ill., on Friday, July 14th, Dr. Charles Johnson, of Austin, Minn., aged fifty-seven years.

Lockary.—In St. Stephens, N. B., on Sunday, August 13th, Dr. Joseph L. Lockary, of Roxbury, Mass., aged forty-five years.

McCorkle.—In Brooklyn, N. Y., on Tuesday, August 15th, Dr. John Alva McCorkle, aged seventy years.

Orr.—In Hot Springs, Ark., on Thursday, August 10th, Dr. E. M. Orr, aged forty years.

Owen.—In Moore, Mont., on Wednesday, August 9th, Dr. Solomon S. Owen, aged forty-eight years.

Peck.—In Oneonta, N. Y., on Friday, August 4th, Dr. Ozias W. Peck, aged eighty-one years.

Pepper.—In Rehoboth Beach, Del., on Monday, August 14th, Dr. Wilbur L. Pepper, of Philadelphia, Pa.

Sharp.—In Nashville, Tenn., on Friday, August 4th, Dr. Charles R. Sharp, aged thirty-two years.

Van Patten.—In Los Angeles, Cal., on Thursday, August 3rd, Dr. Andrew L. Van Patten, aged seventy-two years.

Wynne.—In Walnut Grove, Ala., on Saturday, August 5th, Dr. A. B. Wynne, aged seventy-six years.

PYORRHŒA ALVEOLARIS.

A Review of 1,496 Cases,

BY JOHN A. RODDY, M. D.,
Philadelphia,
Associate in Bacteriology, Jefferson Medical College; Chief Clinical Assistant, Medical Division C, Jefferson Hospital;

ELMER H. FUNK, M. D.,
Philadelphia,
Associate in Medicine, Jefferson Medical College; Physician in Charge, Department for Diseases of the Chest, Jefferson Hospital;

AND DAVID W. KRAMER, M. D.,
Philadelphia,
Instructor in Clinical Medicine, Jefferson Medical College.

The exact date when attention was attracted to this condition is not exactly known. Riggs, after whom this disease is named, recognized it as early as 1844, since in a paper read by him at a meeting of the Connecticut Valley Dental Association, in June, 1869, he stated that he had treated the condition with success for over twenty-five years. Since that time, it has been known as Riggs's disease.

Subsequently, other names, as expulsive gingivitis, alveolar periostitis, pyodental pericementitis, have been suggested. Pyorrhœa alveolaris was proposed by Doctor Rehwinkle at a meeting of the American Dental Association, in 1877, but it appears to have been used by Wedl in a paper published several years previously.

The gross pathological changes by which pyorrhœa alveolaris is recognized vary as the disease progresses. Turner (1) refers to the first stage as "solid stagnation" and gives as its clinical signs—apparently healthy gums from under the edge of which may be squeezed a pultaceous mass composed of germs, later a subacute or chronic gingivitis, the edge of the gum swollen and showing bluish or reddish discoloration and protrusion of the interdental pads; the condition may be general or localized around one or two teeth.

A study of 1,496 cases convinces us that Turner accurately describes the first manifestations of pyorrhœa alveolaris, and that Dowsett's (2) description applies to the next stage of the disease, in which there is gingivitis and the interdental papillæ shrink down or become transversely creased, leaving a space between the teeth; at this stage there is no discharge of pus. Dowsett states that early in the disease absorption of the apices occurs.

In its fullest developed form, the clinical manifestations of pyorrhœa alveolaris are gingivitis with an inordinate tendency of the gums to bleed, shrinkage and recession of the gums from the teeth, forming pockets that contain pus, excrescences upon the roots of the teeth, and eventually looseness of the teeth.

Subsequent developments may show that these signs are not proper criteria upon which to base a diagnosis of pyorrhœa alveolaris, but the most casual or extended perusal of the literature on this subject will indicate that these phenomena are the signs upon which the medical and dental professions base a diagnosis at the present time.

With a few notable exceptions (3) it is generally believed to be a common disease; "ninety-five per cent. of people who apply regularly for dental service have present in their mouths in some location conditions which constitute the principal etiologic factors of peridental inflammation" (Black, 4).

Pyorrhœa alveolaris is not a disease of equal incidence in all classes; it is relatively rare among robust, educated, and intelligent adults, more frequent among delicate, ignorant, and unintelligent adults, common among those afflicted with certain chronic systemic diseases, and most common among the tuberculous, especially the ignorant and destitute tuberculous. We have examined 2,676 persons and find the incidence to vary from two per cent. to eighty per cent. in different classes, as shown in the following table:

Number examined.		Presenting distinct clinical signs of Pyorrhea.
200	Apparently healthy students, 20 to 30 years of age	2 per cent.
100	Ambulant private patients, educated cleanly adults	6 per cent.
300	Medical dispensary patients, adults, acute diseases only	7 per cent.
300	Medical dispensary patients, adults, chronic diseases only, excluding tuberculosis	15 per cent.
1,776	Pulmonary tuberculosis, 506 bed, 1,270 ambulant patients	80 per cent.

If this disease did no more than interfere with mastication it would be serious enough to deserve the attention that has been given it by the dental profession, but an indisputable mass of evidence has accumulated which shows that complications of pyorrhœa alveolaris develop in portions of the body remote from the head, and seriously injure or destroy important organs. Fossier (5) has collected from the literature seventy-five cases of severe or fatal pyogenic infections which appear to have been

complications of pyorrhea or some similar disease of the mouth. After several years of clinical and laboratory studies of this disease in Rochester, Mayo (6) believes pyorrhœa alveolaris to be worthy of consideration among the possible causes of grave gastric disturbances. Niles (7) believes many cases of "idiopathic phlegmonous gastritis" and chronic gastritis are complications of pyorrhœa alveolaris and quotes Tucksdorff and Fitzgerald to support this view.

Of the ninety-seven patients with advanced pyorrhœa alveolaris, whom we were able to study most carefully, forty presented one complication as follows: Arthritis eighteen, gastric disturbance (anorexia, nausea, and eructations) ten, headache, lassitude, and anemia twelve. Twenty presented two complications as follows: Recurrent tonsillitis and gastric disturbance three, recurrent tonsillitis and arthritis seven, arthritis and fever five, gastric disturbance, malaise, and fever four, tonsillitis and cervical adenitis one. Twelve presented coexisting maladies which probably were complications, but the connection could not be established; of these three had recurrent earache, four neuritis, two albuminuria, and three furunculosis.

It is evident that the condition commonly referred to as pyorrhea is a serious one, the incidence and course of which can best be curtailed by a full knowledge of its etiology.

PATHOLOGY.

Until the order in which the involved tissues are attacked has been disclosed, it will be impossible to substantiate or discredit either of the opinions held at present as to the origin of this disease. A considerable number of dentists and some physicians believe as Rhein (3) and Weston (8), "instead of pyorrhœa alveolaris being so common, it is very uncommon and only found after some form of malnutrition has proceeded far enough to destroy the immunity of this end organ tissue." "The progressive pathological stages of pyorrhetic lesions indicate very definitely that one of the most, if not the most important factor is inherent in the tissue itself."

Znamensky (9) concludes from microscopic examinations of sections of the jaw, that the jaw bone is first destroyed by a process of rarefying osteitis. It is first transformed into connective tissue which becomes absorbed. When the bone forming the sockets of the teeth is destroyed, pockets are formed which become infected with pyogenic organisms and a flow of pus ensues. When rarefaction is limited to a part of the bone not containing marrow, cure is possible. He states that these changes are due to local or general conditions and names as causes, osteomalacia, syphilis, and rickets. These investigators fail to record findings which would conclusively support their positive statements.

Of the great number who believe that pyorrhœa alveolaris is due to extrinsic causes which first attack the exposed teeth and gums and affect the apices and alveolar processes later, Turner (10) is the only one who presents post mortem findings to support it. He concludes from post mortem studies of the jaws and teeth of fish, wild and domestic carnivora and herbivora, and man, of all periods from the thirteenth Egyptian dynasty to the present time, that a diet rich in sticky carbohydrates, especially finely ground flour, is the cause.

Confronted with these two opposing views as to the tissues first involved and the consequent relative importance of intrinsic and extrinsic factors in the etiology of pyorrhœa alveolaris, we have conducted our clinical and laboratory investigations so as to determine the relative value of these factors.

The röntgenologists, who in the last few years have added much to our knowledge of pathological processes involving the jaws and teeth, probably can and will supply the information necessary for a more adequate knowledge of the part played by intrinsic tissue defects in the development of pyorrhœa alveolaris.

ETIOLOGY.

One of the most striking findings in our investigation is the greater incidence of pyorrhœa alveolaris among the tuberculous than in any other group. The 300 medical dispensary patients, fifteen per cent. of whom had pyorrhea, may properly be compared with the 1,270 ambulant tuberculous patients, eighty per cent. of whom had pyorrhea. Aside from the fact that one group had tuberculosis and the other did not, no material difference existed.

In contrast to this is the incidence of pyorrhœa alveolaris among the syphilitic. We have inspected 100 adults with active tertiary syphilis, patients upon whom the disease had made a profound impression. Sixteen of these had normal mouths when examined and presented no evidence of a previous pyorrhea; fifteen had pyorrhea. Of thirty-two syphilitic adults (presumably with inherited syphilis) who had conspicuously bad teeth, but had always observed oral hygiene and had been adequately treated by dentists, none had pyorrhea. Osler (11) states: "Of the twenty cases of pernicious anemia which I had under observation in 1909, pyorrhœa alveolaris was present in more than half."

Red cell counts and hemoglobin estimations were made in forty of our early cases, and thirty showed some degree of anemia; in six the red cell count was 3,000,000 or slightly less, in twelve the hemoglobin was below seventy-five per cent. (Dare apparatus), and in four there was a great increase of platelets above normal. Red cell counts and hemoglobin estimations were made in twelve of our advanced cases; all showed some anemia, the average departure from normal being greater than in the less advanced cases.

We conclude from these findings that pyorrhœa alveolaris is more common among the tuberculous than the nontuberculous, that pulmonary tuberculosis predisposes to pyorrhea, or the conditions which favor the development of pulmonary tuberculosis also favor the development of pyorrhea; that the incidence of pyorrhœa alveolaris is not greater among the syphilitic than among the nonsyphilitic, and that syphilis does not predispose to the development of pyorrhea.

We believe these findings indicate that there are marked differences of susceptibility produced by different systemic diseases, so that some systemic diseases, such as tuberculosis, may properly be considered important factors in the etiology of pyor-

rhea, and others, such as syphilis, cannot be so considered.

Whether primary and secondary anemias are predisposing causes or complications of pyorrhœa alveolaris is a problem worthy of thorough investigation. In any event, the frequent association of the two conditions is a fact not to be forgotten in the examination of patients presenting the clinical signs of either.

CHEMICAL CAUSES.

Marked departure from normal in the chemical properties of saliva and buccal secretions has been considered by some to be the cause of pyorrhœa alveolaris. It has also been suspected that the disease resulted from the chemical action of citrus fruits when constantly used. Both these theories have been discredited.

The omission from recent literature of any reference to the rheumatic or gouty diathesis apparently indicates a rejection of the older opinion of the dental profession that these conditions were an important etiological factor in pyorrhœa alveolaris. We have observed but eight patients who might reasonably be so classified; two of those had poor teeth, but none of them had pyorrhea.

The incidence of pyorrhœa alveolaris among fifty patients with chronic nephritis under observation, did not indicate that this condition is a predisposing cause.

Examination of the mouths in diabetics showed, in a study of thirty cases:

15 had evidences of slight pyorrhea.....50 per cent.
8 had evidences of severe pyorrhea.....27 " "
7 were negative .....23 " "

Of the seven cases pronounced negative, only three had no traces of pyorrhea. The others had false teeth, but no evidences of the disease; we were unable, however, to get a history of the original condition of the teeth. It may be said there was no relationship between the stage of pyorrhea and that of diabetes.

In reference to age, the three patients in whom there were no signs of pyorrhea were comparatively young, ranging from fourteen to twenty-eight years. The cases were presented by the type of patients usually seen in dispensary practice.

We realize that not enough cases have been studied to warrant definite conclusions, but it is of interest to note the comparison of the percentages of the diabetics when placed alongside those of the tuberculosis column, discussed in detail under the heading of predisposing causes; showing that eighty per cent. of the 1,776 tuberculous patients examined had evidences of pyorrhea.

If we consider oral sepsis and pyorrhœa alveolaris different stages of the same disease, then in the study of its etiology we must consider the statements of Lane, Hunter, Pritchard, and others (12) who believe that the alimentary toxemia brought about by intestinal stasis is the cause of oral sepsis and pyorrhœa alveolaris. We have not yet been able to investigate directly this phase of the subject, but our work has brought out a fact that seems suggestive, a relationship noted by the writers mentioned, between intestinal stasis, alimentary toxemia, oral sepsis, arthritis, and tuberculosis similar to that observed by us between pyorrhea and tuberculosis.

VITAL CAUSES.

Attention has been recently fixed upon Amœba gingivalis Gros, which was heralded as the specific cause of pyorrhœa alveolaris. No better denial of this could be made than the recent statement of Smith and Barrett (13), that there are cases of pyorrhœa alveolaris which are not due to amœba. They still believe, however, that the vast majority of cases are caused by amœba.

There is strong evidence that few if any cases are caused by amœba. Williams, Sholly, and Rosenberg (14) report having made 995 smears from the superficial margin of the gums of children between five and fifteen years of age who presented no pus pockets. Sixty per cent. of all the children examined harbored amœba and twenty-nine per cent. of them had apparently normal mouths. In these cases the institution of oral hygiene without emetine, reduced the number of amœba carriers one half; oral hygiene plus emetine reduced the amœba carriers ninety per cent.

An organism which can exist in the mouth of twenty-nine per cent. of a large group of children, in such abundance that a superficial smear discloses it, causes no discoverable injury, and disappears in half the cases when a chronically dirty mouth is made clean, is primarily a saprophyte and not likely to possess specific pathogenic properties.

An organism, present in such a large number of mouths and capable of migrating to the tonsil and there causing changes productive of goitre, as has been inferred, would make the incidence of Graves's disease much greater than it is. Smith, Middleton, and Evans (15), in their latest communication, appear to have greatly discounted the possibility of amœba being the cause of pyorrhea. Smith and Weidman (16), Ribbert (17), Jesionek and Kiolemengolon (18) have reported post mortem findings of Endamœba mortinatalium Smith in the parotid glands, kidneys, and liver of infants under circumstances suggesting that syphilis predisposes to amebic infestations. This tends to discredit amœba as the cause of pyorrhea when considered with our observations that syphilis is not a predisposing nor an exciting cause of pyorrhea. We know emetine destroys amœba and have all regretfully learned that emetine is not a specific cure for pyorrhea.

Superficial scrapings from the gums of 100 pyorrhea patients were fixed, stained, and examined and none showed amœba. Twenty-four patients with advanced pyorrhea and sixteen with early or moderately advanced pyorrhea were repeatedly examined for amœba by the method recommended by Bass and Johns, before, during, and after treatment. Of the twenty-four advanced cases seventeen showed amœba before treatment, of the sixteen early and moderately advanced cases four showed amœba before treatment. The twenty-one patients infested with amœba were first put on emetine treatment alone, which caused complete disappearance of amœba, but did not improve the pyorrhea.

BACTERIA.

Beginning with Leuwenhoeck (19), almost innumerable studies of the bacterial flora of the mouth in health and disease have been made. More than a hundred varieties have been found, any of which may be present in the absence of disease. Many pathogenic and nonpathogenic staphylococci, diplococci, streptococci, bacilli, spirillæ, and leptothrices are included. No particular species or group of organisms has been shown to predominate in pyorrhea. Allen (20) states: "The flora of several pockets may vary greatly." Noguchi (21) and Ozaki (22) have studied the spirillæ found in the buccal cavity and have not established specific relationship between them and disease. Ozaki has also investigated those organisms which can be cultured only anaerobically. Goadby (25), who pointed out the necessity of using culture media of different degrees of acidity and alkalinity in order to cultivate the maximum number of bacteria from the mouth, believes an organism morphologically similar to Ducrey's bacillus of soft chancre is the causative organism of many cases of pyorrhea.

Numerous recent observations suggest that certain staphylococci, diplococci, and streptococci are more frequently responsible for the infectious complications of pyorrhea than other organisms. We have examined and compared 3,000 slides, uniformly smeared with buccal secretions and scrapings from the gums and teeth of 200 normal persons, 100 pyorrhea patients, and 100 patients having gingivitis or oral sepsis.

These examinations seem to show very clearly: 1. There are variations in the total number of organisms present in the mouth of healthy persons, there is a maximum number compatible with health, when organisms are present in excess of this number, oral sepsis results. 2. There is always a total number of bacteria in oral sepsis far in excess of what is present in a normal mouth, more than ninety per cent. of cases of pyorrhea showing a bacterial flora indistinguishable from the flora of oral sepsis. 3. Washing the mouth and brushing the teeth with water or any dentifrice after meals will always reduce to normal an excessive bacterial flora. 4. Spirillæ and staphylococci are more frequently found and form a larger proportion of the whole bacterial flora in pyorrhea and oral sepsis than in normal mouths. 5. The result of vaccine treatment suggests that staphylococci, diplococci, and streptococci are the most frequent causes of complications. 6. No legitimate distinction can be made between oral sepsis and pyorrhea, oral sepsis being the first stage of the disease commonly referred to as pyorrhœa alveolaris. We agree with Brown (26), who, after an extensive bacteriological study, states that while a large number of organisms have been isolated he cannot attribute a specific etiological role to any one of them.

When our knowledge of the incidence, etiology, pathology, and the effect of treatment is collated with Dr. O. M. Leiser's deduction that only twenty per cent. of the population of the United States use a tooth brush, it strongly suggests that in the vast majority of cases two equally important factors are necessary for the development of pyorrhœa alveolaris, 1, certain systemic diseases; 2, a chronically superabundant bacterial flora of the mouth.

DIAGNOSIS.

It appears that the manifestations upon which a diagnosis of pyorrhœa alveolaris is usually based—separation and recession of the gums from the teeth, the presence of pus in the pockets so formed, excrescences on the roots of the teeth, looseness of the teeth, and an inordinate tendency of the gums to bleed—are the late manifestations of a chronic disease, the etiological factors of which have been active for many weeks or months before such changes are produced. When these signs appear, irreparable damage has frequently occurred and treatment must be severe and prolonged in many cases. An inquiry directed to numerous dentists, to our own patients, and to those of various other physicians, has elicited the information that comparatively few physicians recognize pyorrhea or refer patients afflicted with it to a dentist until the disease is far advanced; that many dentists do not recognize the frequency of a remote cause and complications that require a thorough medical examination to disclose and medical treatment to correct. From the information we have collected, a conservative estimate would be that among educated well to do patients at least half the cases of pyorrhea reach an advanced stage before they are recognized or treated; among the poor, the ignorant, and the dispensary patients, the great majority of cases have progressed to a far advanced stage before they are recognized or treated.

The irreparable damage to the teeth which inevitably ensues when pyorrhea is allowed to progress, the consequent interference with mastication, digestion, and nutrition, the occasional development of grave systemic complications, and the resulting impairment of general vitality and immunity make the recognition of this disease in its earliest stages most desirable.

The diagnosis of pyorrhea in its early stages will be accomplished only when careful inspection of the mouth becomes a part of every medical examination, when we cease thinking of loose teeth, receded and bleeding gums as the criteria of diagnosis, and recognize less conspicuous signs as equally significant.

When gingivitis is observed, its cause must be sought for and corrected. It may be an expression of disturbed metabolism, such as is most commonly observed during pregnancy; it may result from anemia, primary or secondary; it may accompany diabetes, gout, or pulmonary tuberculosis; it may be a purely local condition, due to locally acting physical, chemical, or vital causes—in any event gingivitis is one of the frequent predisposing causes of pyorrhœa alveolaris; usually it is the earliest clinical sign of the disease.

Oral sepsis must be considered an early stage of pyorrhea. When accumulations of soft white or yellowish matter between the teeth are apparent, the microscopic examination of smears taken from the gums is superfluous—there is always an excessive bacterial flora. There is a distinct relationship between the bacterial flora of the mouth and pyorrhea. No precise method of determining the number of bacteria or the number which should be

considered abnormal has been established. No doubt in time this will be done, but by numerous examinations of both healthy and diseased mouths, we learn to distinguish the normal from the abnormal, not with the degree of accuracy that might be desired, but sufficiently well to afford information of diagnostic value to compensate, in many cases, for the time, trouble, and expense.

Anatomical deformities (including cavities and malposition of the teeth) frequently afford a most favorable site for the lodgment and development of bacteria; as the physician's method of examination sometimes fails to disclose such as are apparent to the dentist, all cases of pyorrhea should be referred to the latter. When the signs of pyorrhea have been observed and a local cause discovered or apparently excluded, a search for remote or systemic causes and complications is indicated. A physician usually discovers pyorrhea when consulted in regard to some other infection or systemic disease; it is then that systemic causes of pyorrhea and complications are most frequently sought for and treated, and the examination should always include an examination of the blood for anemia and a search for signs of pulmonary tuberculosis.

Unfortunately many dentists have not yet realized the importance of referring patients with pyorrhea to a medical diagnostician for examination. It is highly desirable that the professions cooperate in the diagnosis of this disease. Rhein (3) has indicated the futility and danger of failing to differentiate this from other diseases, as follows: "In studying the dental path as an avenue of general infection, it is of the utmost importance to dissociate what is known as pyorrhœa alveolaris from either an ordinary alveolar abscess or its more insidious and dangerous type of an infected zone around the end of a root with no pus formation and no sinus, known as a dental granuloma."

TREATMENT.

The effect of various forms of treatment was studied in fifty cases of advanced pyorrhea. Preliminary examinations disclosed the presence of amœba in seventeen of these cases. Emetine was administered subcutaneously, injected into each pocket, and used as a mouth wash in solutions of different strength; it was also given internally.

From one third to one grain of emetine two or three times a day, for an average period of ten days was the practice in all but ten cases; the latter received maximum doses three times a day for one month.

All the cases that showed amœba before treatment failed to show any after the first week of emetine administration, whether hypodermically, into the pockets, or by mouth.

Microscopic examinations were made two weeks after the last dose of emetine had been given and again four weeks later. Of the seventeen patients who harbored amœba before treatment and showed none one week after treatment, six showed amœba again two weeks after treatment, and these six and two more showed amœba six weeks after treatment. In spite of the disappearance of amœba, emetine, alone, did not cause appreciable reduction of the bacterial flora and did not in an appreciable manner affect the course of the disease. Similar observations on the failure of emetine permanently to rid the mouth of amœba have been made by numerous investigators, notably by those conducting the research, still in progress, of the U. S. Public Health Service and the Department of Health of the City of New York (23).

We have failed to observe the beneficial effect of emetine in reducing the bacterial flora of the mouth that has been accredited it. Attempts to elicit germicidal power *in vitro* have all given negative results. Wherry (24), in discussing the germicidal power of emetine, states that Vedder found the addition of two per cent. of the fluid extract of ipecac to agar exerted a great inhibitive and germicidal action upon Bacillus typhosus, Bacillus paratyphosus, Bacillus dysenteriæ, and Staphylococcus pyogenes aureus.

Sterile agar liquefied and cooled to 45° C., was rapidly mixed with a quantity of the alkaloids of ipecac equivalent to two per cent. of fluid extract of Brazilian ipecac, charged with typhoid and paratyphoid bacilli and staphylococci, and poured into plates. Another set of plates was made by depositing the organisms on the agar after it had solidified in the dishes. These tests were repeated, using two and five times as much emetine. In all, 200 plates were made and comparison with their controls of agar containing no emetine failed to show appreciable germicidal power. Tested according to the Hygienic Laboratory method of determining the carbolic acid coefficient, one to 25, one to 150, one to 100, one to 150, and one to 200 aqueous solutions of emetine failed to kill the typhoid bacillus in fifteen minutes. Kolmer and Smith (27) have reported *in vivo* tests using the tetanus bacillus and Bacillus anthracis, which showed that emetine is not germicidal for these organisms.

Weston (8) admits that it is not probable that emetine exerts direct germicidal effect, but he believes there is a demonstrable lessening of amœba, reduction of the bacterial flora, reduction of pyorrhea, and an improvement in the tone of the gingival tissue surrounding the pockets after the administration of emetine, in many but not all cases. He explains the mode of action in the following words: "Its action is strongly suggested by an immediate change in the phagocytes found in the contents of the pyorrhea pocket, for these undoubtedly form one of nature's chief defenses against the majority of the mouth organisms. We are not certain what the mechanism is, though it seems to be an increase in the stickiness or adhesive property of the surface of the phagocytes, for in these cases after the use of emetine, they, the phagocytes, will be found to contain much larger numbers of organisms."

We have under way an investigation of the effect of emetine on phagocytosis, following the technic of Wright and of Ross, but have not yet made sufficient observations to comment on this view. Our study of smears from the mouth and pus pockets of pyorrhea patients, before and after emetine administration, did not suggest any such action.

Wright and White (28) have reported the cure

of all cases of pyorrhea treated with intramuscular injections of mercury succinamide every seven days, beginning with half a grain. We have no knowledge of the effect of such treatment.

Treatment with autogenous vaccines made from all the organisms that could be cultivated aerobically on agar, blood smeared agar, and Loeffler's blood serum medium was tried. Vaccine treatment alone did not especially affect the condition in the mouth. In conjunction with oral hygiene and dental treatment it appeared to exert a beneficial effect in twenty per cent. of advanced cases, the most conspicuous influence being the amelioration or cure of complications, presumably due to staphylococci, pneumococci, and streptococci. Bertrand and Valadier (30) believe sensitized vaccines very much superior to nonsensitized vaccines in the treatment of pyorrhea.

The effect of oral hygiene as the sole method of treatment was studied. The patients washed their mouths and brushed the teeth after each meal. Various dentifrices, antiseptic and amebacidal solutions, and plain water were used. After a few days of this treatment all cases showed more or less improvement, but in no advanced case did it effect a cure. There was an apparent advantage in the employment of all the antiseptic and amebacidal solutions and dentifrices over plain water, but none of the dentifrices showed any superiority over the others or over liquor antisepticus of the pharmacopeia. Similar observations have been recorded by Rosenberger (29).

Dental treatment in conjunction with regular cleansing of the mouth after meals was the most effective form of treatment. By comparing results, it appears that the most beneficial treatment depends upon accuracy of judgment on the part of the dentist in determining the degree to which surgical procedures shall be carried out in a particular case. It seems that improvement or recovery is frequently retarded by failure to remove promptly teeth that eventually must be extracted; at times also teeth are unnecessarily extracted.

Many are pessimistic as regards the possibility of permanently arresting or curing advanced cases. It may be of interest to cite three cases we have had under observation for several years:

Case I. Woman, fifty-six years old, pyorrhea of several years' duration, marked recession of gums, with pockets and excrescences on roots of four lower incisor teeth, all of which were loose; condition complicated by multiple arthritis and secondary anemia. After six months of dental and medical treatment the mouth was clean, pockets were obliterated, bacterial flora was normal, the involved teeth tight and functioning, the blood normal, and the arthritis gone. This condition of clinical cure has continued for more than two years.

Case II. Woman, forty-seven years old, pyorrhea of more than four years' duration, involving six teeth of lower jaw, red, bleeding, receded gums, excrescences on roots of teeth, tortuous pus pockets, and looseness of involved teeth, secondary anemia. Dental treatment was unsatisfactory until three of the involved teeth had been removed. After three months of medical and dental treatment, subsequent to extraction of teeth, clinical cure was accomplished and persisted for a period of nearly three years.

Case III. Man, thirty-two years old, marked recession of gums, slight pus pockets, slight pyorrhea, looseness of three lower incisor teeth, several years' duration, general physical condition apparently normal. Medical treatment not indicated. Dental treatment over a period of two years unsatisfactory until after removal of one tooth, after which clinical recovery ensued and persisted for more than a year.

The effect of various forms of treatment was studied in a group of one hundred which are classified as early cases of pyorrhea—cases in which there is no recession of the gums, no pus pockets, no excrescences on the roots of the teeth, no looseness of the teeth, the diagnosis being based on the presence of an excessive bacterial flora alone, or associated with gingivitis or the accumulation of soft white or yellowish matter at the margin of the gums and between the teeth. Dental treatment without the practice of oral hygiene had no effect on this condition. Medical treatment of coincident diseases, alone, had no appreciable effect. Various mouth washes were tried and none of them, without the aid of a tooth brush, was as effective as brushing the teeth with plain water. Regular washing of the mouth and brushing the teeth after meals in every case was sufficient to establish an apparently normal condition in all cases where a toxic or infectious systemic disease was not discoverable.

In every case of pyorrhœa alveolaris observed, both early and late cases, in which there has been amelioration, arrest, or cure, regular cleansing of the mouth has been part of the treatment, and no method or combination of methods has produced desirable results without it. The cases observed, in which treatment ameliorated, arrested, or cured the condition, maintained their improved status as long as regular cleansing of the mouth was practised and relapsed when cleansing of the mouth was omitted. This experience is but a repetition of the long established and generally known fact that cleansing of the mouth and brushing the teeth regularly is a potent measure in the preservation of the teeth and of health. The extent to which the dental and medical professions have failed to apply this knowledge in practice is incredible. It would be interesting and instructive to read a report of a commission composed of dentists appointed to visit the hospitals of the United States to inquire into the provisions for the care of patients' teeth while in hospital, to inspect recorded physical examinations, and to examine the mouths of patients, the majority of whom in the natural course of events spend from two to four weeks in a hospital and then return to labor.

Equally interesting information may be gained by questioning a dozen individuals who have many times been in a dentist's chair and yet never cleanse the mouth nor brush the teeth.

It is not sufficient to tell a patient the desirability of regularly cleansing the mouth and brushing the teeth and the consequences apt to arise from a failure to do so; it is imperative that they be kept under observation until influence has firmly established the habit of properly cleansing the mouth and teeth. Of those requiring such care many are adults with whom the failure to observe any toilet of the mouth is an inveterate habit; this, in spite of good intentions, leads to frequent or continual disregard of advice, unless they are impressed by frequent examination. Brushing the teeth, at first, is frequently a painful and disagreeable procedure, and this is

another reason why they need repeated encouragement and advice.

When prescribing a tooth brush, it is necessary to specify the kind and method of using and storing.

CONCLUSIONS.

1. Pyorrhœa alveolaris is not a specific disease; its chief etiological factors are: 1. An excessive bacterial flora of the mouth; 2, deviations from normal of the affected tissues brought about by certain diseases.

2. Oral sepsis is the first stage of pyorrhea; the etiology of both is the same.

3. Pyorrhea can be prevented by regular cleansing of the mouth and teeth.

4. The detection of all the etiological factors in the majority of cases of pyorrhea requires a thorough dental and medical examination. Whenever possible an x ray examination should be made.

5. Acute recurrent gingivitis or chronic gingivitis or a persistent excessive bacterial flora of the mouth is a clinical sign of this disease.

6. Systemic complications are rare in the early stages and frequent in the late stages.

7. Coincident systemic diseases are frequently associated with pyorrhea.

8. There is no specific method of treatment.

9. The three indispensable factors in the treatment are: 1. Training the patient regularly to cleanse the mouth and teeth; 2, the institution of whatever dental treatment may be indicated; 3, medical treatment of coexisting systemic disturbances or disease.

10. Emetine may well be employed as an adjunct on the principle that it will do no harm and may possibly in some cases be beneficial.

11. When infectious systemic complications exist, an autogenous vaccine is indicated and even in uncomplicated cases will at times accelerate improvement.

We wish to acknowledge the assistance given us in this investigation by Professor S. Solis-Cohen, Professor R. C. Rosenberger, Professor W. M. L. Coplin, and other gentlemen too numerous to mention.

THE PREEXISTING CONDITION OF THE INJURED.

A Medicolegal Study from the Standpoint of Employer's Liability and Accident Insurance,

BY G. R. DORÉ, M. D.,
Bordeaux, France.

Under the term preexisting pathological condition or state of health are united a number of pathological conditions, which always have a common character from the fact that they existed *before* the receipt of the injury. They may be congenital or acquired diatheses, at times some temporary general affection, at others simply an affection involving a single system, a single joint or organ. The abnormal state of health previous to the injury may be latent or patent, that is to say, it is present at the time the injury is received or is brought into activity as the result of the injury. It may be in indirect or direct relationship to the causative factor, viz., the injury. With a beginning which is variable, it need not of necessity cease with the recovery from the trauma and may very well continue long after the effects of the latter are recovered from.

In Germany, the law pays no attention to the pathological antecedents of the subject, and whether or not the consequences of a trauma are aggravated by the fact of a preexisting disease, that the working incapacity is prolonged, that the fatal outcome is hastened from this fact, or from an intercurrent disease, the right of the injured to his indemnity in full remains. The consequences of a trauma are undoubtedly greatly influenced by preexisting pathological conditions or predispositions, but the abnormal recovery of the injured is considered, in German law, as being derived from the injury *per se* and, consequently, the full right to recover remains.

In Belgium, in about seventy per cent. of the manufacturing companies and various industrial enterprises, the state of the workingman's health is examined at the time he is engaged, and since this point is covered and it is tacitly understood that the employer can by this examination protect himself, it follows that the most recent law, that of December 28, 1903, does not take the preexisting state of health of the injured into consideration. The latest French law, that of April 9, 1898, appears to leave the preexisting physical condition of the injured open to debate, as will be seen by the extracts of decisions rendered by the courts. On the other hand, the previous condition of health of the injured is taken into consideration by the courts of Switzerland, Italy, Sweden, Finland, and Luxemburg.

The fifth paragraph of Article V of the Swiss law of June 25, 1880, on the civil responsibility of manufacturers, declares that the responsibility of the employer shall be considerably reduced, if wounds or lesions previously received by the victim have exercised any influence on the later injury and its consequences, or if the health of the injured has been weakened by the previous exercise of his profession.

According to Soldan such legislation is only just, because the working capacity of the laborer, who formerly received corporal lesions, is not as good

as that of a workingman who has never been the victim of an accident, and the employer in whose establishment a new accident occurs cannot be held liable other than for the damage imputable to this, the subsequent injury. If, for example, a laborer had already a hand mutilated from a former accident, he would probably be more awkward and thus more exposed to future injury, than a man having his members intact, but the employer at the time another accident occurs, cannot be held liable for the aggravation of the danger. In the same way, a workingman who has lost one eye will often not be particularly hindered in his work from this fact, and his wages will not be affected. But should he lose the second eye, it would not be equity to blame all the consequences of the resulting complete blindness on the second injury giving rise to the loss of the remaining eye.

A more doubtful case would be one in which the consequences of an accident are aggravated, not by the result of a former injury, but by congenital infirmity, for example, a predisposition to tuberculosis. In this case there will not be, generally speaking, a plea for a reduction of the indemnity, unless the congenital defect can be considered of a nature to diminish *per se* the working capacity or the probable duration of the life of the victim.

From the purely medical standpoint, the question of the preexisting condition of the subject raises the entire problem of the etiology in general, that is to say, the science of the causes of disease; or perhaps, it were better to say, the respective value of the divers sorts of causes, what might well be called their hierarchy. In point of fact, the various causes of disease are far from having the same value. In some we recognize only the power of predisposing to disease and thus we shall also study the part played by predisposition. Others are conditions without which the disease could not exist, and these can be termed necessary effective causes. The third class are the true determining causes, of much greater import since they give rise to the disease. They differ from the preceding since they are governed by chance and usually represent an absolutely fortuitous contingency. If the determining cause is, as has been so often said, the last straw that broke the camel's back, the animal must be mightily laden, as is the part played by the necessary efficient cause. From this we can readily fancy what may be the part played by predisposition.

In what class can we place a trauma, which is to be considered only as an intercurrent state? I shall leave aside cases in which the trauma may have played the part of a predisposing cause by creating a point of lessened resistance and by preparing the soil for other causes. There is no reason in this case for limiting the influence of the trauma, since acquired traumatic epilepsy has been known to be transmitted by heredity. In order better to fix our ideas, I shall, after a brief consideration of predisposition in general, examine in a small class of medical affections, the part played by each of these types of causes.

Predisposition. Before considering special cases relative to the preexisting physical condition, it is essential to come to an understanding of the definition of morbid predisposition, likewise its limits and its proof. Littré defines predisposition as "the patent or occult effect which, under the influence of predisposing causes, takes place in the body more or less constantly in a lapse of time of varying length, at degrees of divers intensity, according to the individual." Predisposition does not have any prodromal signs, even distant, of the disease which is to come. Neither is it a morbid imminence immediately preceding the affection. Predisposition is a premorbid state, a morbid aptitude, a special defect of the organism in question, which only makes itself evident by the frequency of diseases of the same order in the same family. It is not sufficient to create the disease and only await the determining cause in order to cause it to bud forth. It is an individual congenital condition, often hereditary, consisting in the fact that physiological excitants provoke an abnormal reaction and that the conditions of existence supported without inconvenience by the majority of people engenders in the predisposed various diseased conditions.

If the predisposition cannot be located in any organ, there is then a predisposition to a constitutional affection, or, on the contrary, there may be a visceral predisposition. In truth, the difference is far from being marked from diathesis or temperament.

When the court asks if there was any predisposition, this simply means whether or not the victim presented before the accident any signs which would lead one to foresee in the near future and without trauma, the occurrence of the disease, but also often it will interpret as simple predisposition the lesion which manifests itself by no involvement of the professional capacity of the laborer, thus confounding the latent state with predisposition. The essential character of predisposition is to be eminently variable. Idiosyncrasy is merely another term to express the individuality of the predisposition. It is the particular manner belonging to each individual of being influenced by agents capable of affecting him. From the fact that a person is predisposed, it does not necessarily follow that the disease will develop. There is nothing absolute or necessary in the relationship between predisposition and disease. On account of this very variability of their pathogenic action in different individuals, morbid hereditary or acquired predispositions should not enter into account when making a medicolegal estimate. All persons are equal before trauma and there only exist individual susceptibilities and relative immunity.

It is quite as perplexing to prove a predisposition as it is difficult to demonstrate its essence. An organism cannot offer better proof of its predisposition to a given affection than the ultimate development of the disease in question, no other proof can cause certitude, and all theoretical convictions are as *nil*. We know very little about predisposition to most diseases, such for instance as cancer, although Freud and Kaminer have endeavored to discover the biochemistry of the tissues which are thus predisposed. In general pathology, the notion of debility, the renal debility of Castaigne, appears to me to realize the type of predisposition. Unfortunately, it will be a long time before this debility can be placed in evidence.

In other words and briefly, predisposition is

synonymous with potential state, and is the reverse of the formed, that is to say, clinically appreciable lesions. Simple predisposition should never be allowed to enter into the case by the court, the determining cause being the only one of importance. If, as has been said, the predisposed person is a candidate, this certainly does not imply that he is a postulant, and the term, elected, which implies a selection, is certainly much more just for designating the person upon whom this cause has fallen.

The first class is composed by the so called parasyphilitic diseases, comprising locomotor ataxia and general paralysis of the insane. In these affections we well know the principal etiological factor, which is syphilis, since Fournier and Erb proved by statistics that lues is at the root of these maladies, and it is for this very reason that Fournier called them parasyphilitic.

Clinical investigation is far from always revealing a syphilitic origin of tabes or general paralysis because it is often a difficult matter to discover syphilitic antecedents of old date, as the patient frequently denies infection, either intentionally or from ignorance. But now we can resort to the procedures of the laboratory, which absolutely demonstrate the enormous proportion of parasyphilitic affections which have specific infection as their origin. It is well known, too, that every syphilitic does not acquire either locomotor ataxia or general paralysis, and carefully prepared statistics covering a large number of cases observed at the Claybury Asylum, by William Mott, demonstrate that the number of syphilitics who become general paralytics amount to only about two per cent. Clearly this proportion is relatively small and will serve as a basis when we attempt by a calculation of approximate probability to estimate the medicolegal value of syphilitic predisposition in the question of general paralysis. Now, since all syphilitics do not become tabetics or general paralytics, it is because syphilis is not everything etiologically, and it requires something else to cause the development of parasyphilitic affections, in other words, a necessary complement. Unfortunately, this necessary efficient cause, or determining cause, if you like, is defined with difficulty. Why, in some cases does the syphilitic virus become localized in the cerebromedullary axis, producing very special lesions, always localized and always identical? The truth is, we do not know. Every syphilitic under the same conditions of treatment is capable of manifesting a gumma, while not every syphilitic will produce a diffuse meningoencephalitis. There is something hidden, which the most minute investigations have not been able to reveal nor can it be experimentally reproduced.

It seems, under these circumstances, that there is no very big place for trauma in the genesis of parasyphilitic diseases, and in point of fact, this very question has been greatly discussed. Unreservedly admitted to the same standing as other common predisposing causes before the laws of employer's liability were promulgated in civilized countries, its role has since been denied with much vigor. In the first place, there are cases which may very properly be qualified as pseudotraumatic. By serious clinical examination, by pathological considerations and experiments, it has been proved that these cases of so called traumatic locomotor ataxia or general paralysis are in reality nothing more or less than instances of these processes of syphilitic origin which have been brought to light by a trauma. In these cases, the former physical condition is simply a beginning of the affection which is detected and revealed by a retrospective inquiry, which is always delicate and particularly arduous, especially when we are dealing with an organic disease of the nervous system. All the efforts of the expert should centre toward the proof of existence of an anterior tabetic condition, or that of a paralytic state which has remained latent. Of this state we know absolutely nothing, unless it is revealed by some fortuitous circumstance. The victim tells us that he worked normally and may produce certificates showing only the fact of his being hired by other employers. These certificates have not the value of a medical examination and merely signify that the laborer, at the time they were given him, did not present any of the symptoms that a medical man might have easily detected. The statements of lay witnesses are equally valueless.

Since we have become aware of the frequency of early tabes, which can be detected by a few discreet signs, and remains unknown to the patient during an almost indefinite time, it is now more frequently discovered. In a large number of cases, Hitzig, Schittenhelm, and Kurt Mendel have demonstrated the presence of symptoms, which logically could be considered to belong to a fully developed locomotor ataxia, long before the trauma was received. Mendel points out the frequency, in the antecedents of tabetics, of pains which have been qualified as rheumatic, but which, when details are given, resemble extraordinarily the pains of locomotor ataxia. Maynaud goes a point farther and considers as diagnostic errors affections in which surgical measures have been resorted to, for example perforating plantar disease mistaken for a suppurating corn, etc. Consequently, the discussion has waxed high between the partizans of traumatic tabes and experts imbued with modern theories.

There is, however, an almost mathematical fact which should, in many cases, remove all doubt. It may be summed up by saying that, in these cases, the question of a preexisting locomotor ataxia is merely one of dates. A well advised medical man would never admit that the latent period could be reduced to a very short time or that the pathological process could develop in a few days. There is always a minimum delay, indicated for each disease by the average of minimum delays, in the generality of antecedent observations a delay which is always the same, that no force can influence nor can it be overstepped by jurisprudence, even if the principle of the preexisting physical state should some day be admitted.

In order better to illustrate this dictum I will here cite the case reported by Thoinot, Gilbert-Ballet, and Dupré.

Case I. A laborer, aged forty-four years, perfectly well previously, it would appear, since he worked on roofs, was crushed in the left inguinal region by an automobile. At a date which was not precisely fixed, but was certainly less than twelve days after the accident, the patient, while in the act of getting up, fell to the floor. This was a sign of motor incoordination because the giving way of the legs

is looked upon as a transitional sign between the preataxic and the tabetic periods of the disease. Twenty-nine days later, paralytic disturbances were discovered, and the next day tabes was confirmed. Forty-two days after the accident, the Argyll Robertson sign was positive in the right eye, and some time later, beside an aortic dilatation, there was a deepening of the first sound at the apex along with a mild dysarthria. The case was lost by a verdict on January 3, 1911, and in the higher court on appeal.

Case II. In another similar case reported by Verger, the patient, a woman, aged twenty-eight years, with a syphilitic husband, was retained in bed for fracture of the right patella, and after the cast was removed she was unable to stand. Careful clinical inquiry revealed attacks of pains occurring without apparent reason. These were erratic and of the pseudorrheumatic type, but the neurologists were of opinion that clinically they were fulgurant pains.

Without clinical control, with the very sudden onset of the morbid symptoms, both these cases might well increase the number of traumatic locomotor ataxia cases already recorded. There is no means of foreseeing that the incoordination and the trauma may both reveal and aggravate it at the same time. More than the trauma itself, I believe that immobilization resulting from the injury should be incriminated medically, but not juridically as a factor. Sachs, Freund, and Mendel have insisted on its unfortunate influence on tabetics and report cases where the subjects had been able to lead their normal life until an accident immobilized them, after which they became incapable of any work. It is just these very pseudorrheumatic affections which cause confusion in the minds of the judges and, consequently, hurt the cause of the preexisting health, which it was in the first place necessary to eliminate. It is hardly necessary to say that these considerations apply only to cases where the tabes comes on too soon after the accident.

The same degree of certainty is far from existing in cases in which the appearance of tabes is late or relatively so. The purely traumatic origin of tabes cannot be at once rejected and the clinical investigation may be absolutely negative in results. But this brief study of the so called cases of traumatic tabes has at least the advantage, that from the scientific standpoint at any rate, there does not exist a case in which the trauma can be properly assimilated to the necessary efficient cause which occupies, as I have pointed out, the second place in the hierarchy of causes. Since, on the other hand, I have endeavored to show that the role of the predisposing cause was filled almost exclusively by syphilis, there remains only one other part for trauma to play, and, in fact, trauma appears as a determining or efficient cause, bringing to the predisposed person a help to other causes.

The question of the preexisting condition of health in *general paralysis* is divided into two very distinct parts: 1. The question of whether or not the predisposing cause, namely, syphilis, constitutes a preexisting state; and, 2, the question of the existence of a general paralysis before the receipt of the injury and appearing clinically afterward; in other words, cases where, to my way of thinking, the preexisting state exists only from an abuse of words.

1. Does syphilis constitute a preexisting state in general paralysis? Here, again, the great predisposing cause, the only one, so to say, is constituted by syphilis. But beside this cause, although greatly remote, other predisposing causes are to be found, such as heredity, alcoholism, and the various poisonings. But no more than in the case of tabes can a syphilitic be considered as a latent general paralytic, and the necessary cause of general paresis—syphilis—is not in itself the efficient cause. The proper soil is required, although as yet it is badly understood, such as cerebral heredity, which renders the outbreak of general paresis possible. Nothing gives any clue as to the nature of the necessary efficient cause and the candidate for general paralysis is in no way to be distinguished from ordinary syphilitics. In order to recover damages it seems to me that what is to be considered is the preexisting state from the viewpoint of physiology, and not the former state from the etiological viewpoint. But still, experts are to be found who maintain that general paresis is always of syphilitic origin and only syphilitic, and they systematically refuse for this very reason to give any part to the trauma in their report of the case, no matter how small. To my mind this is an abusive interpretation. On the contrary, it is enough that the necessary facts are ascertained, in order to admit, juridically at any rate, the existence of traumatic general paresis. According to Ribierre (*Annales d'hyg. pub. et méd. légale* 1907, 1908, and 1909), we should, nevertheless, practically indicate the fact of predisposition, but this conclusion must not make us reject *de plano*, the diagnosis of a traumatic affection. And what is more, it is our duty to assure ourselves whether or not the injured person is a syphilitic.

We have plenty of autopsy reports and histological examinations of cases labeled posttraumatic general paresis and of alleged general paralysis without the trauma, and it would indeed be interesting to compare these records in a careful way. In a general paralytic who received an injury, Vigouroux and Naudasher found some softening, a leptomeningitis and a more marked inflammatory process in the left frontal region. Vigouroux and Hérisson found a hematoma of the dura mater, and adhesions of the latter membrane to the fractured parietal bone in a case where mental disturbances were present before the injury. Briefly speaking, we find in these cases localized lesions, while in general paralysis the lesions are generalized. According to Marchand, they may well become generalized, but produce, even anatomically, only a pseudo-general paralysis.

There is a question which comes up apropos of these results of autopsies, namely, Can we found a solid diagnosis and conclude as to the existence or nonexistence of a preexisting state, in cases of general paralysis from the macroscopic results, as indicated by Martin and Ribierre in cases of traumatic cerebral hemorrhage? In other words, if traumatic general paralysis is admitted, do the lesions here found differ greatly from those of ordinary diffuse meningoencephalitis? I think that this may be answered in the negative, although Collet encountered a predominance of lesions of the ependyma to the detriment of cortical lesions in a traumatic case. Luzenberger believes that when the trauma is followed by cachexia, the cell changes, represented by a peculiar polar distribution of the chromatophile sub-

stance, may completely resemble those produced by some serious general process, such as general paresis. However, the localization of the lesions of meningoencephalitis at a point corresponding to the trauma received on the skull, would lead us to favor a traumatic origin and the probable preexisting integrity of the brain. As to the aggravating influence of trauma upon a preexisting cerebropathy, be it either manifest or latent, it is unreservedly admitted, as abundant proof shows. This aggravation shows itself in general paresis by a much more rapid and particularly acute evolution of the disease after the receipt of the injury.

2. Quite different is the question, whether or not a general paresis existed or had already begun before the receipt of the injury. There certainly existed a general paralytic state in these cases, but such instances are not within the limits of the question, as it is the preexisting state that concerns us, and we are dealing rather more with pseudotraumatic affections having previously appeared. Frequently the subject will be considered by witnesses of his ordinary life, and in perfect good faith, as in excellent health before the injury took place, and inquiry in this direction may indicate that this was true, when in reality he was already in the grasp of the disease. In other cases, there is a rapid development of the symptoms of general paralysis after the trauma, so that the traumatism and the development of the paresis coincide. If the appearance of the paretic symptoms takes place the day following the injury, or even a few days later, the expert would naturally conclude that there was a preexisting latent paretic state, and although the subject may not have given evidence of previous disturbance, there is a sudden outburst of the general paralysis.

The trauma is only the efficient cause which gives rise clinically to a diffuse meningoencephalitis in a syphilitic. The intermediate period is here much too short for the condition of affairs to be otherwise. Here the trauma is responsible for revealing the true condition. From the fact that it can be shown that the general paresis had begun before the receipt of the injury, it does not follow that the subject has no right to recover damages, if it can be proved that the trauma exercised considerable influence over his working incapacity, due in itself to the paresis, but by which the genesis of this incapacity was hastened. Gerlach is of the opinion that it matters little whether the trauma provokes rapid or a slow development of the paresis, when the gravity of the prognosis is considered.

It is certainly more embarrassing when a person, syphilitic or not, in apparent good health manifests after a cranial trauma a series of little nervous and psychic disturbances, followed later by a classic general paralysis. Here the efforts of the expert should be directed to the state of apparent good health existing before the accident, and it will require all his sagacity. The majority of case reports are silent as to the disturbances of the prodromal stage of general paralysis, but an attentive examination would have detected them in the midst of this good health. The phenomena to be looked for are the very minute disturbances of dementia, neurasthenia, or cerebral excitement. In one case, Régis was able to prove that the patient, seven or eight months before the receipt of the injury, wrote queer letters, neglected to pay his debts, which he had always been prompt in doing, and put letters received in his pockets without opening them. Continuing his inquiry, Régis examined the letters written by the patient and found that words were omitted, so that the results obtained amply demonstrated the reality of an incipient general paresis and the widow lost her case for damages.

Thus, according to Gerlach and Euzière, we may correctly suppose, although the question is not as yet fully settled, that the trauma will not give rise to general paralysis unless the central nervous system was the seat of latent paralytic lesions before the accident. In order to recover damages, the victim must show that the accident has been the cause of the morbid phenomena and of the resulting incapacity to work.

The second class of affections now to be considered is composed of what may very properly be termed as arteriosclerotic diseases. They have this as a common character, that the arteriosclerosis forms a predisposition such that the part played by the efficient cause is greatly reduced, while the predisposition is everything. It is quite evident that a person, whose arteries are calcified, whose kidneys are in a bad state, is more greatly exposed to rupture of the vessel walls, even from a slight cause or one which is not even perceived. It is particularly in these cases that the disproportion of the part played in reality by predisposition and the very small part, theoretically negligible, of the efficient cause. A person falling dead upon the receipt of an insignificant trauma may very well have succumbed upon the occasion of almost any physiological act, but the family are so hypnotized by the accident, on which their attention is always riveted, that they overlook the really important cause. The frequency of arteriosclerosis is so great that there is hardly an autopsy of a subject over fifty years of age where some evidence of this morbid change cannot be found and, consequently, on account of this frequency it plays a large part in the evolution of many diseases. Two only need concern us, namely, cerebral hemorrhage and a neurotic state whose prognosis is largely influenced by the preexisting arteriosclerosis. I refer to neurasthenia, or other neurastheniform states. The predisposition created by arteriosclerosis has here such importance as a cause over all others, even that of trauma, that the necessary efficient causes are greatly reduced in value. It is usually a sudden increase in the blood pressure and a diminution of the resistance of the vascular walls that here represent the efficient causes, conditions which are clearly ill defined and difficult to demonstrate. Thus arteriosclerosis, as soon as it comes into play as a predisposing factor, takes a prominent place, putting to one side all other conditions. Without it, it would require a trauma of extraordinary violence to provoke disorders in an arterial system which, so to speak, flees from shock. There are, perhaps, other phenomena which we ignore, because Lejars, in his experiments on traumatic subcutaneous ruptures, noted that, contrary to what has been frequently upheld, a preexisting change in the arterial

walls was not found in the majority of cases; and Lang, in a case of aneurysm from contusion of the abdomen, particularly insists on the fact that neither arteriosclerosis nor syphilis was involved. As far back as 1865, Broca and Chauvel were of the opinion that the majority of cases of rupture of the aorta from trauma occurred in subjects whose arteries were diseased.

At present we should be less positive on this subject, especially concerning arteries of medium calibre. Studying the action of trauma on viscera already the seat of disease, Payhaubert did not find any mention of a preexisting arteriosclerosis in the cases reported in the literature. Likewise, Dubujadoux was unable to discover any evidence of arteriosclerosis in a case of traumatic hemorrhage of the omental vessels. A case was observed by Demoulin of rupture of the aorta in a laborer twenty-seven years old, where it was shown that the subject had an atrophic chronic aortitis, probably heredosyphilitic in origin. An annual payment had been allowed by the court and a decision of the Court of Appeals confirmed it, esteeming that there was no reason to take the preexisting state into consideration. Thus, contrary to what it might seem logical to admit *a priori*, arteriosclerosis is wanting in many cases of traumatic hemorrhage without solution of continuity, where we should logically expect to find it, and its role seems more marked, as far as a general disease is concerned, in general processes, such as those which undoubtedly intervene in the genesis and aggravation of traumatic neurasthenia.

In this very completely documented report read before the second Congrès de médecine légale, Martin and Ribierre endeavored to estimate, beside the proofs of a preexisting arteriosclerosis, the respective part played by the traumatism and pathological condition of the subject, in cases of cerebral hemorrhage. In order to demonstrate with certainty the part played by the arteriosclerotic predisposition, these writers brought forward two lines of proof; the first, which is only one of probability, is based on the relatively frequent coexistence of other hemorrhages of the same age or old foci in the same subject. The second proof of predisposition is furnished by autopsy or operative interference. The former still furnishes the index of probability from the fact of the localization of the hemorrhage because, should it occur in the central nuclei, the part played by the trauma in the etiology of the hemorrhage should be admitted with only the greatest reserve. After the site, the evidence that the hemorrhage took place from newly formed vessels should make us cautious against an abusive interpretation of the part played by the trauma. It is well known that the fragility of the bloodvessels is greatest in the newly formed vessels which are found in patches of pachymeningitis in alcoholic subjects and epileptics. Clearly their rupture often occurs spontaneously, or a very slight trauma may cause a meningeal hemorrhage in these subjects. Consequently it is the reality of the trauma that the expert should endeavor to demonstate, if he desires to establish the fact that the rupture of the fragile newly formed vessels is the result of an accident and not the natural outcome of the morbid changes presented by the subject. Afterward, a histological examination of the cerebral substance, the presence of a renal lesion, a hypertrophy of the heart, and pathological changes in the cerebral vessels compose a series of proofs of predisposition to a hemorrhagic processus. The autopsy should be complete, and particular attention paid to lesions of nephritis and cardiac hypertrophy.

It is particularly in central hemorrhage, also termed late traumatic hemorrhage, that the relation between the hemorrhage and the trauma is, in the majority of instances, hypothetical, and in the others, indirect and subordinate to etiological factors of a complex nature, and of an importance quite equal to the trauma itself.

The cases submitted to the expert will be different when, instead of autopsy findings, we are dealing with purely clincical data. A clinical analysis of the antecedents of the subjects, an etiological inquest of the functional symptoms, will be of much less value, but is the only resourse when the patient survives. To reply to the second question relative to the respective parts played by the trauma and preexisting physical state in traumatic cerebral hemorrhage, Martin and Ribierre give a minute analysis of sixty-one cases, forty-eight only of which are considered. In many instances the relationship appears to the vague and uncertain. In a case due to Michel, the subject, an alcoholic, presented a hypertrophy with dilatation of the heart and a mitroaortic atheroma. In Kob's case the heart was flabby and fatty; in Mazurkiewicz's case there was atheroma of the aorta and vessels of the apex. In Cevidalli's case there was chronic nephritis, while in the one published by Vial, the subject, aged fifty-two years, was an alcoholic. The remaining cases are quite as instructive. The first case, one of Abadie's, was a man fifty-two years old with a senile arrythmic myocarditis; there was hypertension with hard arteries and a change in the heart sounds in his second case. In Bousquet and Auglada's case the patient, a man aged sixty-two years, presented a tension of 21 with a pulse of 70 and an aortic murmur.

From their study, Martin and Ribierre conclude that there exists a predisposition to cerebral hemorrhage, due to lesions of arteriosclerosis visible at autopsy or by disturbances of the arterial tension which can be detected by sphygmomanometry. They conclude that the preexisting state has here such importance that the efficient cause usually escapes the most minute investigation. It is commonly by an abusive extension of facts that primary importance is attributed in these cases to an insignificant trauma, the reality of which is not any too well demonstrated. This severe analysis should be followed by the expert in all such cases, and the results transmitted to the proper legal authority.

It must be admitted, in reaching the reports of these cases of traumatic cerebral hemorrhage, that the reality of the traumatism is far from being always demonstrated with all the evidence desirable. In Michel's case there was only an indirect shock on the head from an iron bar; in Kob's, a simple

blow from the fist; in Frank's, the shock of a piece of wood on the head; in Bousquet's and Auglada's, a fall into a hole; in Mazurkiewicz's, a simple fall with no further details. Now, it is hardly possible to admit that the trauma alone was sufficient to produce a cerebral hemorrhage in all these cases, admitting that all the subjects were in perfectly healthy condition. As to the necessary efficient cause, it is never, be it understood, mentioned in the report. Consequently, the true part played by the trauma in cerebral hemorrhage appears as merely an efficient cause, fortuitously brought to bear simply to form a cumulative etiology fatal to an already undermined organism.

(*To be concluded.*)

THERAPEUTIC APPLICATIONS OF HUMAN THYROID EXTRACT.

By S. P. Beebe, Ph. D., M. D.,
New York.

A number of years ago, the writer mentioned in a paper read in a symposium before the Section in Biochemistry of the American Association for the Advancement of Science, that from the standpoint of physiological economy and therapeutic efficiency no form of thyroid medication was in the same class with human thyroid extract. At that time some calculations were made to determine how small a dose of this proteid was required to meet the physiological needs of a person suffering from myxedema. The writer had had an opportunity to test the efficiency of various forms of thyroid preparations in two cases of typical myxedema with classical symptoms, and it was found that when administered hypodermically a relatively very small dose of this proteid would control the symptoms of the disease more effectively than animal extracts given either by mouth or by hypodermic injections.

A great deal of experimental work has been done since that time in attempts to isolate the physiologically active substance from the thyroid gland. The most striking of these experiments are probably those of Kendall working at the Mayo clinic, who believes that he has isolated the functionally active iodine group from the cleavage products produced by hydrolysis of thyroid proteid with sodium alcoholate. He gives figures to show that this substance is very high indeed in iodine content, and suspects that it may be a combination of iodine with an indol group in the molecule. So far as the writer knows, these results have not been confirmed up to the present time, and the investigator, himself, has had some difficulty in repeating the experiments. This work, if confirmed, is of course of fundamental importance, but the question arises whether or not the cleavage products so obtained may not be produced under the conditions of the experiment, but not necessarily duplicated in the metabolism of living animals. It is certain to my mind from work of many investigators, as well as my own, that the iodine proteid combination isolated from the thyroid gland has the physiological effect which we ascribe to thyroid function, and in this connection I wish to quote from the article previously mentioned:

The facilities for the absorption of this material are apparently not such as to provide for taking up a large quantity in a short space of time, and the question arises as to how large an amount of this material must enter the circulation in a unit of time in order to carry on satisfactorily the thyroid function. As far as we can judge from experimental conditions, the sensitiveness of different animals and different individuals to thyroid shows wide variations. In some instances I have produced noticeable effect in a human adult by the hypodermic administration of five mg. of protein prepared as above from normal glands containing between 0.32 and 0.36 mg. of iodine in each gram of fresh gland. In other cases, 0.01 gram has shown decided activity, while 0.06 gram usually shows quite pronounced effects, even in normal persons. In several cases of cretinism I have found 0.01 gram of this protein has been effective in completely ameliorating symptoms. In myxedema, 0.03 gram of these proteins taken each day has kept the symptoms completely under control. On the other hand, I have had patients taking 0.5 gram daily for considerable periods without producing any other effect, as far as could be determined, than that of general well being. There is then a very wide variation between the limits of the amount required to maintain health and the amount which a patient may take without causing marked physiological disturbance. Furthermore, if so small a quantity of protein as that mentioned is sufficient to satisfy the needs of the average patient for thyroid function, we need not suppose that the venous blood or the lymph coming from a thyroid should contain very much of this secretion. Three hundredths of a gram of this protein put into the blood which flows through a normal gland in one day (and this has been estimated by Kraus to be fourteen times the total volume of blood in the body) would not give an appreciable addition in iodine. It furthermore indicates what a large factor of safety there is in a normal thyroid gland. Such a gland would average about twenty grams in weight, from which there might be obtained three grams of the protein above used, or one hundred times the quantity sufficient to fill the demand for this secretion in the case of a myxedematous patient.

Since the isolation of iodothyrin by Baumann it has been believed that the thyroid function might be served by the use of this small fragment of the protein, but it is my belief that the thyroid function is not in all respects to be filled by this fragment. The physiological, as well as the most effective, method of administering thyroid secretion to an animal is to give the same biologic sort of secretion by hypodermic injection. I have in many instances been unable to get the same quality of effect or to produce the same change in the metabolism of an animal by administering thyroid by mouth as could be obtained when giving it directly into the circulation. We do not know on what tissue or set of tissues the thyroid secretion acts. It does not seem to me probable that it is to be compared to the exclusive action of secretin, but rather that most of the tissues in the body are in some way affected by this substance, perhaps in part through the medium of the nervous system. We know that it is connected in some way with the function of oxidation in the body. By the administration of thyroid to a cretin or patient with myxedema it is possible to increase the absorption of oxygen from twenty to seventy-five per cent. There is a corresponding increase in the amount of heat given off from the body. The removal of the thyroid from an animal will cause diminution in the absorption of oxygen, which may be again increased by thyroid feeding. Administration of thyroid to a normal animal will cause an increase of from ten to forty per cent. in the oxygen demand. In comparing myxedema with Graves' disease, we find a very marked contrast in this respect. With the former the absorption of oxygen, the food requirement, the energy exchange is often not more than forty to fifty per cent. of the normal, while in the latter we see these factors very much increased, occasionally to nearly double the normal. We are again confronted by our lack of knowledge when we find that these changes do not always follow thyroid administration.

For the purposes of these tests the animal glands and the human glands were subjected to the same

processes of preparation. The method has been described elsewhere and will be repeated in this article. Those who have had much experience in dealing with myxedema patients, or with the use of thyroid in the treatment of cretins, are always gratified by the remarkably beneficial effects which follow this form of medication, so that thyroid extract comes as near to being a real specific treatment for these difficulties as is found in medicine. The results are dramatic in their seeming completeness, and yet we cannot observe these cases closely without being aware that the administration of animal extracts does not completely restore the patient to health. The administration of animal extract by hypodermic injection will produce fairly effective therapeutic results in the beginning, but if continued gives rise to annoying local reactions at the point of injection. This annoying local reaction is somewhat more disturbing than I have observed in other forms of alien protein administered in this way.

To obtain the most satisfactory therapeutic effect with thyroid extract, it is the writer's belief that human thyroid protein must be administered by hypodermic injection. This is in no way a criticism of the present methods of thyroid therapy. It is an interesting observation which seems to have a physiological basis and is borne out by clinical tests. During the last six years the writer has had an opportunity of using human thyroid extract by hypodermic injection in a variety of conditions, and its efficiency is so marked that it has seemed worth while to describe briefly some of these conditions and to suggest that in difficult cases it may be a suitable medicinal substance for the physician to use in combating disease in spite of the very great difficulties which necessarily surround its preparation. During this time abundant confirmation has been obtained of the observation that both qualitatively, which is most important, and quantitatively, which has no particular significance, it is far superior to the thyroid preparations commonly used in treatment.

The writer has observed many patients in whom the usual thyroid extracts afforded only partial relief and in whom the relief was accompanied at times by undesirable effects in other directions, who have been effectively treated with human thyroid extract injections without these untoward and disturbing symptoms shown by the heart and nervous system. Thyroid extract is now used in a great variety of conditions. In fact, some men, notably Hertoghe, find in its use a considerable measure of relief for a large proportion of the ills that flesh is heir to. Certain it is that in the last ten years thyroid extract has gained entrance to the treatment of conditions covering a considerable portion of the field of practice. As an example, there are many observations in the literature made by writers of this country and abroad regarding beneficial effects obtained in the toxemia of pregnancy. This effect is so marked that many practitioners find it of the greatest help in this condition and place great reliance upon it. The writer has not had large opportunity to test human thyroid extract in these conditions, but some observations which have been made indicate that thyroid extract, prepared from the human thyroid gland, is more effective than animal preparations in relieving the symptoms of toxemia. One case of this kind has been reported in the literature by Dr. George Gray Ward. This patient could not be relieved to such a degree by animal extracts as to make it safe for the pregnancy to continue. The administration of human thyroid extract by hypodermic injection made it possible for the patient to go to term and be delivered of a healthy child. For the details of this case the reader is referred to the original article. In brief, however, it was found that if these injections were suspended or an attempt was made to substitute animal extracts, the blood pressure increased, the volume of urine very markedly decreased, quantity of nitrogen excreted dropped within twenty-four to forty-eight hours to less than one half and even as low as one quarter of the amount formerly excreted. The patient was violently nauseated, with severe headache, and approached a condition of toxemia where convulsions were imminent. Very promptly after the administration of hypodermic injection of human extract the volume of urine increased, the blood pressure fell, the nitrogen elimination rose, headaches ceased, the nausea and vomiting stopped, and the patient was able to take a satisfactory amount of food and resumed a fair condition of health.

In another instance thyroid administration in the usual form had been begun at the fifth month because of the toxemic manifestations. This was continued for a period of two months without interruption, but with increasing severity of symptoms; so marked indeed that the patient had one mild convulsion. The human thyroid injections were begun at this time to the practically complete relief of the patient during the balance of the term.

In the ordinary hypothyroid conditions of a classical type accompanied by the usual manifestations of a mild myxedema or cretinism, this extract has proved its effectiveness. In one instance a patient with fairly typical myxedema undiagnosed for some time later had his disease properly diagnosed and thyroid treatment instituted. This patient, curiously enough, was one of those who showed marked sensitiveness to thyroid extract, although manifesting typical and well advanced symptoms of myxedema. Such a condition has been observed by many writers and, although not common, is nevertheless of sufficient frequency to put distinct limitations upon animal thyroid extract treatment in these conditions. This patient could take only three two grain tablets, containing five per cent. of pure thyroprotein, each day. This was not a sufficient amount effectively to control the myxedematous manifestations. A larger dose than this caused disturbing heart reactions and nervous symptoms which made the patient very uncomfortable. When, however, human thyroid extract was administered by hypodermic injection, in addition to the animal extract given by mouth, the symptoms were completely controlled and the myxedematous swellings cleared up, the skin became smooth and soft, the hair grew in and lost its dry, coarse texture, and the patient was relieved.

In another instance myxedematous manifesta-

tions in a man of thirty-five years of age, much undersized, were noted somewhat over six years ago. The usual thyroid extract was begun and continued for three months. Some relief was obtained, but it was not satisfactory to either physician or patient. At that time hypodermic injection of human thyroid extract was begun in addition to the animal extract given by mouth. Following these injections a satisfactory control of the symptoms followed. This patient has continued these injections during the last six years. For the last five years he has received one injection daily of approximately one c. c. of a 0.33 per cent. solution. On two or three occasions during this period the patient has been without the injections for a period of ten days to a month, and in spite of the fact that he has continued to take the animal extract by mouth, the former distressing symptoms—dryness of skin, falling of hair, and myxedematous swelling—have begun to manifest themselves. In this instance, therefore, it seems necessary for the health of the patient to continue the injections regularly. Because of the considerable length of time during which these injections have been continued, this case seems to be a notable one. Human thyroid extract has not been used to any extent in therapeutics, and this patient is undoubtedly unique in the kind and extent of the treatment he has had.

The dermatologist has found that thyroid extract has a beneficial effect in many skin diseases and is accustomed to rely upon it. The writer has not had an opportunity to observe personally many instances of skin disease treated with thyroid extract. In one instance a patient having scleroderma had been treated with thyroid for a number of months without much relief. Human thyroid given by hypodermic injection was begun and continued for some months with marked beneficial effect, not only to the skin lesion, but to the general health of the patient. This patient lived in a distant State and returned to her home, and has not continued the injections since that time. After stopping the injections the condition recurred in its former severity.

In the hypothyroid conditions accompanying goitre, or as a sequel to a former active hyperthyroidism, and in those somewhat ill defined and intangible clinical conditions in which there are manifestations of both hyperthyroidism and hypothyroidism, the writer has had a considerable experience in noting the beneficial effects which may obtain from the administration of human thyroid extract. These patients form a group troublesome to the physician. They require careful study and analysis and their treatment is not infrequently a matter of therapeutic experiment. Human thyroid extract has a place in therapeutics with these patients which is not to be overlooked.

With another group of patients the writer has had opportunities to observe effects that seem to be almost specific in their sharpness and promptness of result. This is a large group, and every physician, whether interested or not in ductless gland conditions, has to deal with patients of this sort. This group is composed of women, varying in age from twenty to over forty years, who have at the menstrual period a regular recurrence of toxic manifestations. They are likely to have severe headaches, profuse menstrual flow, extending over from six to eight days, nausea and vomiting at times, and are so much depleted by this experience that they have during each month only about two weeks of really normal life; the other two weeks are filled with the premenstrual psychic and physical disturbances, often of a severe grade. The period of actual flowing is often accompanied by colicky pains, great physical weakness, backache, with a loss of an unduly large quantity of blood; then comes a period of a few days' gradual physical, mental, and emotional recovery. Such patients are really only fifty per cent. efficient. Even during the two weeks of comparatively normal life they may be below par in physical strength, the constant drain of repeated, profuse hemorrhages leaves them anemic, nervous, fretful, and a prey to intercurrent physical difficulties, as well as psychically depressed. The writer does not refer, in citing these patients, to those women who have a malposition of the uterus, or to abnormal conditions within the uterus itself, such as fibroids, polyps, or an endometritis. As I have seen them they have been the rounds of physicians to obtain relief, not infrequently a slight malposition of the uterus has been held responsible for all the untoward symptoms which they show, and they gladly submit to various operative procedures in the hope of obtaining relief. Curettage is frequently done, and occasionally with some benefit for a month or two. But the vicious circle of events returns and recurs with all too regular frequency. This condition of affairs is occasionally seen in young women under twenty years of age. As a rule, the writer sees them somewhat older than that and with a history of some years' standing. Probably no event in a woman's life causes her so much physical and mental distress, and a cycle of events of the character described produces a great psychic depression that extends to some extent even during the nonmenstrual weeks of the month. In some instances they show a kind of sullen resignation toward being a woman, accompanied by an earnest hope for an early menopause. Other symptoms of hypothyroidism are usually lacking.

Although profuse menstruation is generally classed as a hypothyroid manifestation, and the writer has observed it in many instances, yet in far advanced degrees of hypothyroidism the menstrual function is entirely suspended. With the mild degrees of hyperthyroidism the menstrual period is shortened. With the severe degrees of thyroid overactivity menstruation may be entirely suspended for several months. Clinically, therefore, there seems to be a rather marked contrast between the menstrual periods in the mild hypothyroidism compared with the mild hyperthyroidism conditions. The general physical health of the patient, of course, suffers markedly from these recurring hemorrhages. The administration of the usual tonics does not seem to be of much benefit. Some medicines commonly in use may temporarily check the flow, but do not relieve the other physical manifestations, and in no way do they modify the psychic and emotional disturbance which occurs at this time.

The writer became interested in this phase of

medicine by observing how frequently these profuse menstrual hemorrhages occurred in the mild hypothyroid cases. The administration of thyroid extract in the usual forms may afford some relief. This relief, however, in no way compares with the relief to be obtained by the administration hypodermically of human thyroid extract. There may be medicines that work as effectively in these conditions as human thyroid extract, but the writer is not acquainted with them. One typical instance may serve as an illustration. Patient was a young woman, twenty-five years of age. At the age of twenty years, when she was a student in college, she indulged in active physical exercises, and it was believed at this period she suffered a malposition of the uterus, as shown by a marked retroversion. Her menstrual difficulties had begun a year before the time when it was believed the uterus was displaced, and in spite of the physical weakness which developed as a result, she continued her physical work, much to her disadvantage. When she was twenty-one the uterus was replaced in its normal position, she had a vacation in the country, and took various tonics to build up her general condition. Finally she received a prescription containing fluid extract of ergot in order to control the profuse hemorrhages. Neither rest nor medical treatment served to alleviate the situation, and at the age of twenty-five, some years after these previous experiences, she came under the writer's observation. She had lost weight during this period, her menstrual disturbances began six or seven days before the actual onset of the flow, she had headaches, gradually increasing in severity, was sleepless, psychically very much depressed, so that during these days thoughts of suicide were continually recurring; she occasionally had severe nausea and vomiting a day or two preceding the flow. A few hours before the hemorrhage started she had severe uterine cramps and backache. This train of symptoms was usually relieved to some degree after the first twenty-four hours. The flow continued very actively during seven days, with progressive physical weakness at its termination. She was dizzy on walking around, her physical strength would not permit her to have much if any physical activity for the next four or five days, during which she gradually regained vigor and color. On some occasions, after the flow had stopped and she was resuming activity, she fainted at inopportune times. A physical examination revealed no malposition of the uterus, and while the patient was rather weak and flabby, no organic disease was discovered. Hemoglobin was sixty-five per cent. and the red blood count a little below 4,000,000. Ten days before her next menstrual period was expected, she began the hypodermic administration of human thyroid extract. One injection was given each day, each injection containing one c. c. of 0.50 per cent. solution. The first period occurring after the institution of these injections was marked by a complete freedom of headaches, backaches, psychic and emotional disturbance. She had some uterine cramps during the first twenty-four hours of the flow, which continued on this occasion for a period of five days. During these five days it was as profuse as it had been formerly. The afterperiod of weakness was not as pronounced. The same program was instituted ten days before the next period, with the result that there was the same relief as before, with the added effect of diminishing the flow to a period of three days. During these three days the flow was not as profuse as it had formerly been. She recovered fairly promptly and was in good spirits, with the hemoglobin at the end of the period eighty-five per cent. Since that time, a period now of more than a year, she has taken the thyroid extract in diminishing amount, until at present it is found that a single injection given before the onset is sufficient to control the situation. She is now about twenty pounds heavier than at the beginning of the treatment, is a healthy, active woman, whose blood conditions are absolutely normal. She continued vigorous physical activity without discomfort during the menstrual period.

This kind of relief has been obtained in so many cases at different ages that it has become in my experience comparatively easy to control the situation in the type of case described by this means of treatment. The same method of treatment has been used in some instances during the menopause when the uterine hemorrhages, as is known, may continue for two or three weeks at a time and may recur at irregular intervals. The writer has repeatedly seen a prolonged period of this kind cut short within twenty-four hours by one or two injections.

Those whose practice leads them constantly into contact with patients of this sort may have other means of effectively controlling the situation as that described. The writer is not familiar with them, however, and has not found the usual lines of treatment described in literature effective with such patients. In this instance the menstrual function seems to be a toxic manifestation which seriously influences the patient in addition to a very marked loss of blood. The writer is aware that he is describing a therapeutic method which cannot have wide application under present conditions. Nevertheless, the question arises whether it is not possible for many physicians to make use of this method to the benefit of their patients. The preparation of the extract is not a difficult matter to one who is familiar with laboratory procedure, but of course the main difficulty is in securing the human thyroid glands which serve as the basis for the extract. In large cities this should not be an insuperable difficulty.

MODE OF PREPARATION.

The method the writer has followed in preparing this extract is as follows: The glands are carefully freed of all connective tissue, then ground to a fine pulp in a machine. The pulp is suspended in a physiological salt solution of eight to ten times the volume of the gland pulp. The extraction is carried on in the cold for a period of forty-eight hours, when the extract is filtered through gauze and finally through paper. The filtrate is made faintly acid with acetic acid and brought to a temperature on a water bath of 44° C. The nucleoproteid and globulin are separated promptly by this process and washed by decantation. The protein is dissolved by making its suspension in salt solution very faintly alkaline with sodium bicarbonate. This solution is

filtered again through paper and the filtrate again precipitated by making faintly acid with acetic acid. Again the precipitated proteid is washed by decantation. The washed protein is now dissolved in a smaller quantity of faintly alkaline salt solution and nitrogen determinations are made. It has been found that if this protein solution, faintly alkaline, is heated to boiling it does not coagulate nor does the heat destroy the physiological action of the protein. Therefore, instead of filtering through a Berkefeld filter as we have done for a number of years in order to sterilize this solution prior to its injection, we have sealed it in sterile ampoules and then sterilized the sealed ampoule by heating to boiling temperature for a period of fifteen minutes on each of three days. Such a solution is absolutely sterile and causes no irritation when injected and is physiologically as active as we have observed the solution to be when it has been prepared for injection by filtration through a Berkefeld filter. This modification simplifies the process a great deal because passage through a Berkefeld filter is slow and tedious, and while we have done it for a number of years, still we have found the present method superior in every way, and have substituted it for the older method.

THE SYNDROME OF ASTHENIA, OF MENTAL ORIGIN.

By Meyer Solomon, M. D.,
Chicago.

It is well known that peculiar bodily feelings, in fact pronounced bodily reactions, may be induced or aggravated by the mental attitude of the patient. Feelings of asthenia, comprising a syndrome of pseudasthenia or false asthenia, not of a genuine nature, may thus arise, or, having been superinduced by other factors, may be aggravated, or prolonged, or continue to exist after the original inciting agents have ceased to be operative; this aggravation is due to definite mental factors, as in hypochondriasis and in many cases of neurasthenia with its multiple origin.

In these cases we find autosuggestion and heterosuggestion playing a decided role, combined with morbid introspection and selfabsorption, a general state of increased or prolonged emotionalism, with anxiety, watchful expectation, apprehension or fear usually an integral part, permitting suggestion to play freely, and producing an enhancement of the symptoms. Once the symptoms have appeared, there is a veritable vicious cycle—the emotionalism with suggestion increasing the symptoms, in degree or number or both, and the accompanying symptoms increasing the emotionalism and suggestibility. Déjerine and Gauckler have elaborated this viewpoint in their excellent work recently translated from the French by Jelliffe.[1]

Acute emotionalism of itself, especially if prolonged, may cause temporary periods of asthenia or fatigue, as not infrequently occurs after pronounced anger, fear, and similar depressing or exhausting emotions; but the syndrome of asthenia of mental origin which I wish to discuss is not of this simple origin. It is of a more indirect nature, yet the mental factor, the emotionalism, is the specific and original inciter of the vicious cycle, and the asthenia syndrome is definitely present, being a reality. Of course, after the onset of the condition, worry as to its origin and nature—its meaning—may lead to disturbing mental reactions, and may be the beginning of a superadded psychoneurotic state of one sort or another.

The cause of the condition here considered is emotionalism. Worry, anxiety, apprehension — in fact fear or any of its lesser manifestations is the specific provocative agent. This instinct of fear is fundamentally related to self preservation, phylogenetically and ontogenetically, but under the special circumstances of any particular case may be attached to, or arise as a reaction to any of the aspects of modern life in general. Thus the worry may be over the possible effects of the past or present practice of masturbation, of nocturnal emissions, or of interrupted coitus, of the possible effects of illicit sexual relations (venereal disease, pregnancy), business worries (expected failure, results of bankruptcy proceedings, etc.), of possible dissatisfaction with one's career (artistic, scientific, etc.), scruples of one kind or another (religious, moral, ethical), superstitious fears, anxiety concerning the outcome or significance of some physical ailment (heart disease, diabetes or the like), worry over the death of a relative or friend; and so on. The fear, then, is a reaction to desires, wishes, hopes, aspirations, inclinations or dreams, or to conduct or ideas, past, present, or even projected into the future.

PATHOGENESIS AND SYMPTOMS.

It is well known that almost any source of mental unrest, of slight or great degree, may lead to sleeplessness or light sleep with many dreams (which are especially apt to have some connection, distant or remote, with the cause of worry). It is not unusual for a normal person to be so disturbed at night for a few nights or more. Insomnia, therefore, is the result; and as most physicians appreciate, insomnia is frequently due to mental factors.

The degree and duration of this insomnia will vary with the nature of the inciting cause for worry on the one hand, and the makeup of the individual or his tendency to worry on the other. It is thus seen that it is not so much the absolute intrinsic value of the exciting cause or provocative agent, but its relative value to the patient. It is the patient's attitude toward any particular situation, the manner in which he regards it, the significance he attaches to it, which is all important. A relatively insignificant incident or situation may therefore lead to a pronounced reaction, with prolonged worry, especially when the victim is lying in bed preparatory to falling asleep.

Any one who has suffered from insomnia for even a few days should be well acquainted with the symptoms. We can then well imagine a multiplication of these symptoms, in degree and number, in one who has prolonged insomnia plus continual worry. The condition would not be so serious if

[1] *The Psychoneuroses and Their Treatment by Psychotherapy*, Philadelphia, 1913.

the person so affected worried for a time over the inciting factor and then ceased. But a person in such a plight too frequently ceases to worry about the original situation, be it what it may, only to begin to worry about the physical and mental condition in which he soon finds himself, with insomnia and a host of other symptoms. As the newer situation with its many disabling manifestations is more annoying than its predecessor, it strikes more directly at the health and welfare (self preservation) of the patient, and so displaces or represses the former fears and attaches itself more readily to the general fear reaction. The new state of affairs now becomes the great concern and source of worry for the individual, leading to increased insomnia. Where insomnia is much feared, fear and expectation of it at bedtime lead to more decided insomnia.

Now insomnia, if at all prolonged, is the cause of many symptoms; it leads to a host of complaints and greatly aggravates the condition already present. Prolonged insomnia, combined with worry, produces physical, intellectual, and emotional instability. Let us first take up the physical symptoms. Insomnia soon leads to headache, spots before the eyes, dazed feelings, dizziness, sleepiness, loss of appetite, dry mouth, coated tongue, constipation, and a general state of fatigability and exhaustion. Asthenia is one of the most prominent manifestations. Chilly feelings, paresthesias, tremors of the protruded tongue and extended fingers, increased knee jerks, a tired, worn out expression, frequently anxious and drawn, with general aches, weak back, shortness of breath, cardiac distress, sometimes pallor, rapid pulse, frequently lowered blood pressure, with general malaise, lack of strength and endurance, and some loss of weight.

Intellectually the patient begins to show lack of concentration, inability to pursue his work for any length of time, a tendency toward inactivity, and an avoidance of his usual work (as a natural consequence of his general physical and intellectual fatigue). Added to this is emotional instability, with irritability, crankiness, easily aroused anger, grouchiness, with an increasing degree of dissatisfaction, pessimism, mental depression, and a marked tendency to anxiety, apprehension, and worry. Women more than men are apt to cry on slight provocation or for apparently no reason, but really owing to the emotional instability, the general disturbed state, and feeling of unhappiness and depression. The hyperemotional state, consisting of depressing emotions, plays a considerable role in the production and continuance of the visceral and other symptoms.[2]

The patient himself may complain only of the most prominent and disturbing symptoms, such as headache or insomnia or weakness or vague, general complaints. Only by careful questioning are all the symptoms elicited. Frequently the physician, in looking for a physical cause, may neglect to unearth the history of the case, with the demonstration of the worry over a certain situation in life as the original cause of the insomnia and its added symptoms, the forgetting of this primary cause and the subsequent worry concerning the general physical and mental condition. In too many of these cases no cause can be found by the physician, who may then label it "nervousness" and let it go at that. This lack of knowledge of the cause of the condition, with the continuous presence, even exaggeration of the symptoms, added to the conviction that the symptoms are real and not imaginary (for they certainly are as real as any symptoms primarily due to toxemia or other physical factors), leads to increased worry on the part of the afflicted one concerning the nature and meaning of his trouble. Not knowing the meaning, he may indulge in speculation and interpretations based on whatever knowledge he has previously acquired, and it is therefore not astonishing that he gradually begins to fear the onset of insanity, apoplexy, tuberculosis, heart disease, or what not. The examining physician, failing to follow the trail of the mental factor, neglecting the knowledge which as a rule he can so easily obtain by analyzing the case and tracing its history, may, in his examinations for physical factors, by his actions or remarks, suggest various possibilities to the patient.

Sometimes the patient himself, especially in the early stages, vaguely, at other times clearly, recognizes the real cause of his present condition. Such patients are fortunate and help to put the physician on the right track.

It is seen that we already have a full fledged so called neurasthenia or rather so called neurasthenic state, primarily of mental origin. I know that some physicians would even call the earliest stages of the condition here described nothing other than so called neurasthenia. Perhaps I would be willing to label it abortive, incipient so called neurasthenia, or a *forme fruste*. It is not until the latter stages, when the mental condition becomes more characteristic, that the stamp, neurasthenia, may be given to the condition. In predisposed persons so called hysterical and psychasthenic reactions may appear. Full blown hysteria may be aroused even by the extreme emotionalism, and so called psychasthenic states (doubts, fears, scruples, tabooes, anxiety states, and the like) may here have their first setting or resurrection. We must also not forget that the first cause for worry may have been an actual physical disorder. For example, telling a patient in the course of a physical examination for some other purpose (life insurance, entrance to a lodge or fraternal organization, etc.) that his heart is rapid or irritable, or that he has a functional or true heart murmur, may be responsible for the evocation of the sort of reaction described above. Or the knowledge of gastric disorder, heart trouble or the like may lead to uncontrollable worry concerning possible effects. Or the presence of some physical defect may not be a source of anxiety until the asthenic state resulting from worry over external factors or social relationships has been produced.

Just as such a state may eventually lead to so called

[2]Although this aspect cannot be elaborated here, an understanding of the *modus operandi* may be had by a study of such works as William McDougall's *Introduction to Social Psychology*, Sherrington's *Integretative Action of the Nervous System*, Darwin's *Expression of Emotion in Man and Animals*, Pavloff's *Work of the Digestive Glands*, Crile's *Origin and Nature of the Emotions*, Cannon's *Bodily Changes in Pain, Hunger, Fear, and Rage*, Stanley Hall's *Synthetic Genetic Study of Fear*, and the illuminating studies on the vegetative nervous system and the ductless glands. The mental aspects of these cases can be understood by a study of the writings of such psychopathologists as Dubois, Déjerine, Prince, Sidis, and others.

hysteria or psychasthenia, so may manifestations in the latter conditions lead to worry and a resulting asthenia syndrome, even to a mature so called neurasthenia. As an end product, local manifestations may make their appearance in the gastrointestinal tract, cardiac system, genitourinary organs, or elsewhere, but in such cases we have a typical neurosis of one or more organs. Suggestion, with fixation of the attention upon particular organs, abetted by emotionalism, and supported by the particular susceptibilities or reactional trends, physical and mental, determine the subsequent development of the localized manifestations or false organopathies or organ neuroses. Anxiety states are very commonly present.

PROGNOSIS AND TREATMENT.

The prognosis of this disorder varies with the duration and treatment. It has been mentioned that a true psychoneurosis or minor psychosis may blossom forth. The debilitated condition may predispose to tuberculosis or bring such a latent condition to the fore. Likewise the general resistance to physical disease (influenza, etc.) may be lowered. In all, the individual makeup, its type or reactivity, is exceedingly important. If the condition has not been permitted to advance to these complications, the prognosis is excellent in all cases, provided that proper treatment is instituted.

A thorough knowledge and understanding, to be sure, is essential. A thorough and satisfying examination is not only a desideratum, but is necessary. The history of the case and its evolution having been unearthed, and physical causes excluded as the original factors, the matter is thoroughly gone over with the patient and the origin and evolution as elaborated earlier in this paper are explained to him so that he understands and believes it. Although hypnosis and the hypnoidal state may be here added to our therapeutic armamentarium, I have not found it necessary to resort to it in these cases. The patient must understand that you realize that his symptoms are real, not imaginary, but that they are due to insomnia plus worry concerning his symptomatology —in other words, emotionalism; that this worry tends to reproduction and maintenance of his symptoms, and the latter to increase his emotionalism; that the insomnia and some of the symptoms first made their appearance because of the worry about another situation, which, having been disclosed, is now reviewed with him, and which in the course of time was displaced and forgotten; that not having understood the historical background of his present trouble, nor having seen the relationship between the first cause and his present condition, it was but natural for him to endeavor to explain his condition by certain vague fears and anxieties; that if he now endeavors to control his useless worry and emotionalism, the symptoms will be gradually lessened until they disappear. You must, however, assist him by medication. The insomnia must be prescribed for, one of the usual hypnotics being employed. I do not believe in withholding hypnotics in these cases when they are clearly indicated, since the insomnia is the main cause of the other symptoms. Of course the diurnal emotionalism plus the toxic state resulting from disturbed digestion and general metabolic upset are also potent factors to be considered. Hence hydrotherapy, rest, plenty of food and water, treatment for the constipation, headache, and the like may be called for. It will be found, however, that a thorough understanding of the condition, with treatment of the insomnia, will soon, in a week or more, varying with the case, lead to rapid improvement. If a true psychoneurosis has come into being, the treatment is so much the more difficult.

A condition similar to that here described occurs in the early stages or in the course of the major psychoses, such as dementia præcox, manic depressive psychosis, and general paresis, this being frequently due to insomnia or becoming a part of the general picture of toxemia, as, for example, in general paresis.

If the patient himself realizes the cause of his condition, whether vaguely or clearly, the treatment is so much the easier and results are so much the more rapid.

DIAGNOSIS.

Such states of asthenia with its symptom complex as have been here mentioned should in all cases be differentiated from the syndrome of asthenia due to other causes—tuberculosis, arteriosclerosis, syphilis, etc. For this the history is of the greatest service and may be the means of preventing us from making many unnecessary laboratory and clinical tests. In some cases, where the history is not positive and is of too long duration, such tests may be indicated and indeed should be instituted when the least doubt or suspicion exists.

CONCLUSION.

Worry over somatic or external factors may lead to insomnia and the syndrome of asthenia. Worry concerning these symptoms may now take the place of the original causative factor, the patient as a rule not appreciating the relationship. This may be the starting point of true psychoneurotic states. The diagnosis is easy, with the aid of the history and the exclusion of physical disease as the primary cause. Prognosis in uncomplicated cases is most favorable, treatment being simple and results prompt. The mental factor should be thought of, investigated, and weighed in every case of the asthenia syndrome, especially when no apparent cause exists. Insomnia is most potent in producing symptoms and must be boldly and unhesitatingly treated by drugs and otherwise. In these cases successful treatment means that we are frequently aborting or nipping in the bud, so to speak, psychoneuroses and minor psychoses.

Owing to lack of space specific case histories are not here cited. In typical cases, however, it will be found that the brief description of the evolution and symptomatology of the syndrome given is typical and accurate and applicable to practically all such cases. Naturally, there is considerable variation in symptomatology, depending upon the age of the patient, the duration, the special circumstances of the case, and the type and severity of reaction, physical and mental, of the person affected.

1517 South Kedzie Avenue.

DR. S. WEIR MITCHELL.*

A Short Sketch of His Life,

By W. A. Boyd, B. S., M. D.,
Baltimore,

Assistant Psychiatrist, Henry Phipps Psychiatric Dispensary, Johns Hopkins Hospital; Assistant Neurologist, Mercy Hospital Dispensary.

Silas Weir Mitchell was born February 15, 1830, in Philadelphia. He was the son of Dr. John Kearsley Mitchell and Matilda Henry, and came of sturdy Scotch stock who had lived in Virginia before moving to Pennsylvania. His father was a professor in Jefferson Medical College for many years. Weir Mitchell's preliminary education was obtained in the grammar schools of Philadelphia and in the University of Pennsylvania. He left the latter in his senior year on account of ill health.

He felt himself, that in his early studies he was ill taught. He developed slowly and his lessons were a wearisome task. In his *Autobiography* he has recorded that his education began and almost ended in the books of the Philadelphia Library. There he was taken by his father after his mother had locked up the copy of the *Arabian Nights' Entertainment,* which he found and which she discovered him reading.

It was his father's influence which carried him through his teens and enabled him to break the bar of physical weakness and to lay a foundation for the strength of the future in four years spent in a boat with rod and gun upon the rivers near Philadelphia.

He graduated, in 1850, after two years' study at the Jefferson Medical College. His medical education was such as was customary at the time and in no way remarkable. His graduating thesis was entitled *The Intestinal Gases.* His father desired him to become a surgeon, but the idea at first was horrible to him and he fainted so often at operations that he began to despair; but by continually assisting at the surgical clinics he overcame by degrees his horror of blood and pain.

He studied in Paris in 1851 and 1852, and although interrupted much by illness, it was a broadening experience. The decade following his return from Europe was devoted to a growing, but not too engrossing general practice.

In 1852, at the age af twenty-three years, he published his first medical paper. In September, 1853, he was elected a member of the Academy of Natural Sciences, and, in 1857, was one of the founders of the Pathological Society.

In 1862, he entered the army as an assistant surgeon and served until the end of the war. Soon after the war broke out Surgeon General Hammond, at Mitchell's suggestion, established some special hospitals, and during the Civil War Mitchell was in charge of Turner's Lane Hospital, Philadelphia, where he established a special ward for nervous patients.

He contributed much to medical literature. His first book, entitled *Gunshot Wounds and Other Injuries of Nerves,* was written in collaboration with Keen and Moorehouse, and published in 1864. His work, entitled *Injuries to Nerves and their Consequences,* was published in 1872, and his classical monograph, *Fat and Blood,* in 1877; the latter has been translated into French, German, Italian, and Russian.

In 1859, with Hammond, he investigated the arrow poisons, corroval and vao, and was the first after Abbé Fontana and Bonaparte to investigate serpent venoms. With Edward T. Reichert, he isolated the diffusible globulins of the venoms, his studies having an important bearing upon the more recent work of Fraser, Calmette, Keyes, and Flexner and Noguchi. In 1869, he pointed out the coordinating functions of the cerebellum, and with Morris J. Lewis demonstrated that the knee jerk can be reinforced by sensory stimulation.

His book, *Injuries of Nerves and their Consequences,* contains the earliest distinct accounts of ascending neuritis, the treatment of neuritis by cold and splint rests, and the psychology of those who have suffered amputations. He was the first to describe erythromelalgia or red neuralgia, and postparalytic chorea, and, with William Thompson, was the first to emphasize the importance of eye strain and astigmatism as causes of headache. In 1875, he introduced a treatment of nervous disease by prolonged rest in bed, with such adjuvants as optimum feeding, massage, and electricity, the so called "Mitchell rest cure." He was also the first to study the effect of meteorological changes upon traumatic neuralgias, particularly in old amputation stumps.

He was twice president of the College of Physicians and Surgeons, Philadelphia, and was a member of the leading medical and scientific societies both in this country and abroad. He received many honorary degrees, among them being an honorary M. D. from Bologna, and LL. D. from Edinburgh, Toronto, Harvard, Princeton, and Jefferson Medical College.

In 1882, he entered upon his career as a writer of fiction. Some of his novels are *Hugh Wynne, Dr. North and His Friends, Circumstance, When All the Woods are Green, Ronald Blake, The Red City, Far in the Forest, Florence Trescott, The Case of George Dedlow, The Autobiography of a Quack,* and *Westways.* He also wrote several books of verse, among them being *Herndon, The Physician, The Birth and Death of Pain,* and *A Doctor's Century.* His writings, both scientific and imaginative, are fascinating, his style is polished, and his diction finished.

Dr. Charles W. Burr, in his memorial notice of Doctor Mitchell in the *Transactions* of the American Medico-Psychological Association, writes: "The three great qualities of Weir Mitchell were his clearness of mental vision, his emotional sanity, and his capacity for work."

In the Memorial Addresses and Resolutions, Dr. William H. Welsh writes: "Many of his novels contain descriptions of doctors, patients, epidemics, and of historical events which are of distinct medical interest and value." In the same volume, Dr. James C. Wilson says:

> He was certainly the most accomplished physician of our times. In science, poetry, letters, history, and every grace of social life he achieved unusual distinction. He

*Read before the Baltimore Neurological Society, April 20, 1916.

served his country and mankind by brilliant original investigations during the Civil War, and from his earliest days devoted himself to original research, and by example and suggestion inspired others to engage in similar work; but it was as a practitioner of the art of medicine that he manifested those qualities of mind and heart that enabled him for nearly half a century to command the admiration and affection of grateful patients and appreciative professional colleagues in almost every civilized country.

Doctor Mitchell was twice married. He died, January 4, 1914, of influenza after an illness of about one week. He was eighty-four years old.

114 West Franklin Street.

SPASMUS NUTANS.*

By Murray B. Gordon, M. D.,
New York,
Clinical Instructor in Pediatrics, Long Island College Hospital; Associate Pediatrist, Harbor Hospital; Etc.

(From the Department of Pediatrics, Long Island College Hospital.)

Case I. Raymond M., ten months of age. No history of epilepsy, convulsions or mental disorders in family. Both parents healthy. Patient was first child, full term, normal delivery, breast fed every two hours; for past five months had also been getting potatoes and bread. Weight not known at birth. First tooth erupted at six months of age; first sat up at six months, began to creep at seven; no history of convulsions or aural discharge. Mother had noticed that for the past two months, the child shook his head from side to side almost continually during the day. She had not noticed it while the child was asleep. The stools varied from day to day, being green and curdy at times, while the child was constipated occasionally.

Examination showed a well developed child, weighing twenty-three pounds. Head was well shaped, normal in size, anterior fontanelle open; mouth showed three teeth. Eyes did not show nystagmus; accommodation of pupils to vision and light was sluggish. There was a nodding of the head from side to side. The spasms were rhythmical and about forty or fifty to the minute. Occasionally they would cease for a minute or two, but would soon be resumed. Spasms of both hands, of the same character as of the head, were also present. The child was conscious. The reflexes were normal. General examination was negative, except for enlargement of the epiphyses and a distended abdomen.

The mother was advised to wean the baby, as an examination of her milk showed it to be of poor quality. The child was placed on oatmeal gruel, orange juice, white of egg, and whole milk. He also received thyroid extract, one tenth grain twice a day. This was continued for ten days, when elixir of the glycerophosphates of lime and soda, one half dram three times a day, was substituted for it. The thyroid extract was gradually increased until one grain three times a day was given. The lime and soda was given on alternate weeks. The child gradually improved and in about six weeks the spasms ceased. The mother was instructed as to the proper diet and told to return for observation. Six months later, the child was brought to the clinic by the mother, who reported that the spasms had not returned, that the child had gained in weight, and that he then had eight teeth.

Case II. Iris S., fifteen months of age. Family history negative as to syphilis, chorea, epilepsy, or convulsions. Normal delivery at full term; breast fed. Teething began at eight months; child sat up and crept at about the same time. Was just starting to walk. Examination showed a colored child with typical rhachitic symptoms. Head was enlarged, anterior fontanelle open, enlarged epiphyses, pot belly; chest showed rhachitic rosary; child had eight teeth. There were no perceptible tender spots anywhere.

There was a lateral nodding of the head, rhythmical and slow in time. The mother had noticed these spasms for several months. No nystagmus was present. Reflexes were normal.

The mother was advised to wean the child and add fruit juices, cereals, and whole milk to its diet. It also received the compound syrup of hypophosphites. No further history was obtainable, as the child was not returned to the clinic.

Case III. Horace A., two years old, youngest of nine children; no history of syphilis, epilepsy, chorea, or similar disease in family. Full term, normal delivery, breast fed for one year. First tooth appeared at five months of age; did not walk as yet; had been creeping since eight months old. Mother said child was restless at night and that it shook its head when looking at objects. The nodding was not present when the child was asleep. It sweat about the forehead at night.

Examination showed a poorly developed boy, head slightly larger than the normal for his age, anterior fontanelle not completely closed; mouth showed twelve teeth. No lateral nodding of the head was seen until the child's attention was drawn to a particular object. As the child tried to accommodate vision and concentrate its attention upon the object, which in this instance was a pencil, there was a slow rhythmic nodding from side to side, accompanied by a nystagmus of both eyes. The spasms ceased when the pencil was removed from the child's field of vision. The nystagmus was observed to be coincidental with the spasm of the head and at no time was seen independently. There were no spasms noticeable in other parts of the body. The reflexes were normal. General examination demonstrated a typical case of rickets. Heart and lungs were normal. Abdomen was enlarged, spleen normal, liver enlarged, epiphyses enlarged, legs bowed, cervical glands enlarged.

The child's diet was regulated. He was also placed on thyroid extract grain one half twice a day, alternating every week with elixir of glycerophosphates of lime and soda, one dram three times a day. The thyroid was increased gradually to one grain three times daily. The spasms ceased in about two months.

Spasmus nutans is a rare functional neurosis found in children, which consists of an almost continual nodding or shaking of the head. It is also known as head shaking, head jerking, head rotating, nodding spasm, and gyrospasm. It was first observed, in 1850, by Henoch and Romberg, but it was not until Raudnitz had made an exhaustive and detailed study, that the complete clinical picture was appreciated. There have been some later contributions to the literature on the subject, but these are meagre and have not supplied any additional knowledge.

In a recent compilation of 4,000 general cases coming under the personal observation of the writer at the Polhemus Memorial Clinic, which has not as yet been published, the foregoing three cases are the only ones of this type of nervous hyperirritability found in children. The age incidence is between six months and three years. The majority of cases reported have been in children between six and twelve months of age. Cases in the female sex predominated.

In children with this condition, we find a slow rhythmic shaking or nodding of the head, the direction taken being either from side to side or up and down. In some cases there is seen a rotary movement of the neck. Each nod-

*Read before The Brooklyn Pediatric Society, April 26, 1916.

ding revolution has the regularity, precision, and time of the pendulum of a clock. Generally, there are no other rhythmic movements or other phenomena of nervous irritability, though in some cases, as in one of our series, there may be an accompanying spasm of an arm or leg. The mentality of the child is not impaired. During the attack there is no loss of consciousness, differentiating this condition from epilepsy and similar convulsions of childhood. The spasms may be continuous for some variable length of time, cease, and then be resumed. In many instances, attacks are brought on by the child turning its head, or concentrating its attention, in an endeavor to look upon a particular object, or in a certain direction.

In the majority of cases reported, nystagmus has been associated with the spasm of the head. Some observers, among them Raudnitz, consider this more than a coincidence and hold that nystagmus is present in every case of spasmus nutans, and that their contentions can be proved if every case is seen long enough and studied minutely. In two of the cases of our series, nystagmus was not observed. In the case that was studied through practically the entire course, this eye condition was not seen by either the mother or the writer.

There is a difference of opinion among observers as to whether spasmus nutans is a separate clinical entity. It is accepted, however, that it is in no way connected with or related to epilepsy, tetany, or any tetanoid hyperirritability of the nervous system.

Raudnitz lays great stress upon dark rooms and poorly lighted dwellings as being of important etiological significance, asserting that this condition is due to an overexertion of the eye muscles produced by insufficient or bilateral illumination. He explains that under these bad hygienic conditions the child, in order to look at any particular object, has to turn the eyeballs upward or to one side so as to get the proper angle of light. He demonstrated that the spasms disappeared upon bandaging the eyes. While this theory has been accepted in part by others, it is contended that the child must primarily be poorly nourished and physically below par. It has since been proved that in the majority of instances the children affected are rhachitic.

Stamm has demonstrated that there is a "mechanical irritation of certain portions of the cerebral cortex due to a hyperemia of the internal periosteum of the skull resulting from rhachitis." Hochsinger also arrived at the conclusion that the condition is due to rickets, because in fifty cases that he had studied, he found rhachitic changes in all. He is of the opinion, therefore, that the condition should be classified as one of the hyperirritability convulsions of childhood associated with rickets. In each of the three cases reported in this paper, we had to deal with a rhachitic child.

Spasmus nutans is insidious in its onset, and may not be noticed in the first stages. There may be an occasional shaking of the head several times during the day, or perhaps the child is noticed nodding its head after some excitement. Gradually, the spasms appear oftener, the intervals between them shorten, and the active nodding lasts for a longer period. In some instances, the spasms do not appear unless the child's attention is directed to some particular object, and as the child endeavors to concentrate its vision, shaking of the head supervenes.

The course of the condition varies; the longest period in which it persisted was reported to have been two years. No deaths have ever been reported so far as the writer could ascertain in his perusal of the meagre literature on the subject. Our knowledge of definite pathological findings is limited. It is generally accepted that it is purely functional during an irritation of the nervous system subsequent to rickets. The prognosis, therefore, is very good as to the ultimate cessation of the spasms.

The treatment should be directed toward the primary cause. The malnutrition should be corrected, the diet regulated, and if the illumination of the dwelling is at fault this should be remedied. Fresh air and sunshine are imperative. The rhachitic condition can best be treated by the usual remedies. We have found thyroid extract efficacious. This may be given alone or in conjunction with calcium lactate. The elixir glycerophosphates of lime and soda may be given alternately with the thyroid.

PRIMARY PERITHELIAL SARCOMA OF SPERMATIC CORD.

With Report of a Case,

By Adolph Brand, M. D.,
New York,
Chief of Clinic, Department of Dermatology, St. Bartholomew's Clinic; Assistant Attending Dermatologist, University and Bellevue Hospital Medical College Clinic; Etc.

The comparative rarity of new growths of the spermatic cord and the paucity of information in the literature on the subject warrant reporting such cases as come under observation. The textbooks on surgery and pathology make only brief mention of these highly interesting growths. Among 110,000 male patients admitted to the London Hospital in twenty years, Howard collected only sixty-five cases with neoplasms of the spermatic cord. C. Ciaccio also speaks of the extreme infrequency of this condition and cites the statistics of Patel and Chalier as the best. They collected altogether 110 cases, of which thirty-seven were lipomas, seven myomas and myofibromas, twenty sarcomas, and fourteen of mixed type, one carcinoma and eighteen of indefinite variety. Von Schutter reports two cases of tumors of the spermatic cord and emphasizes the scarcity of these growths.

Various types of tumors have been found in the spermatic cord. They include lipoma, fibroma, myoma, myxoma, myxolipoma, myxofibroma, sarcoma and carcinoma. Of the benign growths lipoma is of most frequent occurrence, and sarcoma takes first rank among the malignant neoplasms. Malignant growths of the spermatic cord may develop at any age—one case of a boy of fifteen years is on record—but middle aged and elderly men chiefly exhibit these growths.

Very little is known of the etiology of spermatic cord neoplasms. Recent injuries are credited with being the causative factors in a small percentage of cases, and it is denied that venereal disease plays a provocative role. It is stated by many authors that neoplasms of the spermatic cord usually develop secondarily to such growths in the testicle, but it is conceded by some that the primary origin of the tumor may be within the cord itself.

The case reported here is of interest because the growth seems to have had its origin in the spermatic cord, and because a venereal disease with an unusually severe complication manifested itself only a short time prior to the detection of the neoplasm itself.

Case. The patient, a young man of twenty-eight years, had no previous illness, except a left sided inguinal hernia, for which he was operated on at the age of fourteen years. He contracted his first urethritis two weeks before coming under observation. This affection seemed to have been very mild and received little attention till swelling, accompanied by severe pain, set in in the right ankle and in two of the finger joints of the left hand.

When he presented himself for examination, the findings were a slight mucopurulent discharge from the urethra, showing under the microscope the Neisser organisms and pus cells. The testicle on the right side was normal, that on the corresponding side smaller, round, and hard. The epididymides, spermatic cords, prostate, and seminal vesicles were negative. The right ankle was considerably enlarged, very sensitive to the touch, and locomotion was attended by excruciating pain. Two finger joints of the left hand were also affected, but in a milder degree. There was some elevation of the temperature and gastric distress —the latter no doubt due to the ingestion of fairly large doses of oil of santal.

The patient was confined to bed under treatment, and six weeks later, was walking around with considerable ease and had no demonstrable evidence of his urethritis. Urgent business at this time called him out of town for a few days, during which he indulged in a great deal of walking. Upon his return to the city the left testicle became swollen and painful. He was again put to bed, with appropriate treatment, directed toward the affected organ. In spite of numerous measures instituted to reduce the inflammation of the testicle, the process did not abate; the pain increased in severity to such an extent that slight relief and very little sleep could be induced only by the administration of opiates. A septic temperature set in, and it became evident that a radical procedure would have to be adopted.

Under general anesthesia an incision over the affected side of the scrotum revealed a foul smelling soft mass occupying the entire left scrotal cavity. This was removed, the cord ligated as high up as possible, and the cavity packed. The patient made very good progress after this and left the hospital two weeks later. The mass removed was submitted to Dr. Louis Heitzman for examination, and he reported as follows:

The most striking gross appearance is that of hemorrhagic extravasation, pervading practically the entire testicular structure. Upon microscopical examination hemorrhagic areas are found everywhere, both in the interstitial connective tissue and within the seminiferous tubules, while here and there variously sized blood clots are present. Beside this hemorrhage both the connective tissue and the tubules are infiltrated with inflammatory corpuscles, so much so that the epithelia of many tubules are destroyed, being replaced by pus corpuscles. These changes are more or less universal, including the tunica albuginea, the corpus Highmori, and the different seminiferous tubules. Nowhere is there any evidence of caseous degeneration as seen in tuberculosis or of malignant formation. Diagnosis: Hemorrhagic and suppurative orchitis.

For a year the patient went about his business and then returned, complaining of a mass in the left side of the scrotum, which was giving him slight pain at times and much anxiety. This growth, he stated, became evident about two months after the orchidectomy and was increasing in size.

At this examination the patient's general physical condition was entirely satisfactory and there was no trace of his former urethral troubles. As the scrotum was visualized it appeared to contain two testicles; palpation, however, showed a normal organ on the right side and a mass about the shape and size of a small egg in the stump of the left spermatic cord, adherent to the scrotal wall and painless to manipulation. The glands in anatomical relationship with the part under consideration were not enlarged; a rectal examination showed no abnormal changes and a Wassermann reaction on the blood was negative, as was also a tuberculin test.

A diagnosis of tumor of the spermatic cord was made and the growth was removed. The cord beyond the mass was not involved, and the stump was cauterized with pure phenol. The scrotal cavity showed no signs of suppuration and the incision was closed up, leaving only a small space for drainage. The patient made a rapid and uneventful recovery, leaving the hospital one week after admission.

Dr. Douglas Symmers, of the University and Bellevue Hospital Medical College, who examined this tumor, says, "Specimen consists of an egg shaped mass. On section numerous areas of necrosis are evident and in fact the mass is so soft that frozen sections cannot be made. Paraffin sections, however, reveal the presence of malignant growth, the prevailing cell of which is distributed radiately around thin walled bloodvessels and is perhaps best provided for under the designation of perithelioma or perithelial sarcoma." He assumes that the primary growth was in the testicle, but ends by saying, "The fact remains, however, that the growth now under consideration is malignant. Diagnosis: Perithelial sarcoma of the spermatic cord."

The interesting question here is the primary origin of the neoplasm. Had there not been a pathological examination of the removed testicle, the assumption that the growth had its inception in that organ and that the spermatic cord was only secondarily involved, would be warranted in view of the fact that this is the usual mode of development of these tumors. However, since a very thorough examination of the removed testicle by a pathologist of unquestioned ability, failed to show evidence of malignancy, it must be argued that in this instance the spermatic cord was the primary seat of the growth.

Another salient point in this case is the etiology. Since recent injuries are looked upon as the causative factors in the production of tumors of the spermatic cord in about twenty-five per cent. of the cases, might it not be assumed that the suppurative process in the testicle and the surgical intervention acted the role of trauma in the subsequent development of the neoplasm in the spermatic cord?

More than two years have elapsed since this growth was removed, and the patient is enjoying excellent health and does not show signs of recur-

rence. From the standpoint of the patient's age—only twenty-nine years at the time of the operation—his illness before the tumor developed and his subsequent good health, the case is unique.

The writer takes this opportunity to thank Dr. Terry M. Townsend and his associate, Dr. Julius J. Valentine, for their kind help in the first operation, Dr. Louis Heitzman for his examination of the first specimen, and Dr. Douglas Symmers for the examination of the tumor removed from the stump of the spermatic cord.

HEART DISORDERS IN CHILDREN.

By J. Epstein, M. D.,
New York.

Disorders of the heart in early life differ from disorders of the heart in later life in their etiology, pathology, symptoms, and signs. A conception of cardiac diseases and disturbances in the child based solely on a knowledge of cardiac abnormalities in the adult will frequently lead to errors in diagnosis.

Infancy and early childhood is the age of congenital heart lesions, as a result of malformations or endocarditis during intrauterine life. Youth is the age of inflammatory heart lesions due in the majority of cases to rheumatic infection. Adult life is the age of degenerative heart lesions which usually follow such chronic diseases as arteriosclerosis, chronic interstitial nephritis, syphilis, alcoholism, plumbism, and chronic bronchopulmonary affections. Functional cardiac disorders are more frequent in early life, while structural cardiac changes are more frequent in later life.

The subjective symptoms of cardiac diseases and disturbances such as faintness, tiredness, palpitation, dyspnea on exertion, and precordial pain or distress are not as significant in the diagnosis of heart diseases in children as in adults. Children, as a rule, pay little attention to their subjective feelings of discomfort or to symptoms of ill health, because they have little knowledge of the normal functions of the body and of the normal standard of health. The most important symptom of cardiac disease in children is the feeling of tiredness. These children, when observed, are found to get tired out on the least exertion. They are dull, apathetic, sleepy, and do not indulge much in play with other children. In cases of functional cardiac disorders, the children are usually bright, nervous, irritable, unable to sleep well at night, and they cry frequently.

In the diagnosis of cardiac disorders it must be primarily determined whether they are due to structural or functional abnormalities; the latter are more frequent. In every case the heart should be carefully examined for signs of endocarditis, myocarditis, pericarditis, and functional disorders. The mistake is frequently made in the routine physical examination that the heart is examined mainly for murmurs of endocardial origin, while signs of myocarditis, pericarditis, and functional derangements are entirely overlooked. The normal functions or attributes of the heart which are essential to a normal circulation are:

1. Stimulus production; the power of producing or originating a stimulus in the sinoauricular node which is the starting point for cardiac action and controls its rate and rhythm.
2. Excitability or stimulus reception; the power of the heart to receive a stimulus.
3. Conductivity or stimulus conduction; the power of the heart to convey the received stimulus from one part to another.
4. Contractility; the power of the heart to contract when stimulated.
5. Tonicity; the power of the heart to retain a certain amount of contraction even during cardiac rest or diastole.
6. Coordination of functions; the unity of action of all the cardiac functions.

One or more of these fundamental functions of the heart may become abnormal as a result of structural changes or nervous instability, and give rise to a group of disorders of which the most important are the following:

1. Sinus arrhythmia, tachycardia, bradycardia, auricular fibrillation, and auricular flutter.
2. Extrasystole.
3. Heart block.
4. Pulsus alternans.
5. Functional dilatation and functional murmurs.
6. Incoordination of functions.

Sinus arrhythmia, or youthful irregularity, or vagus irregularity is common in children. This irregularity arises in the sinoauricular node, which is the normal pace maker of the heart and is under the control of the vagus. It is characterized by rapid heart action during inspiration and slow heart action during expiration, normal rate on holding the breath or on very rapid breathing. There may be occasional missed beats or a long pause between normal beats. Tachycardia in children is frequent during emotion, excitement, pain, and fever. Bradycardia is usually present during convalescence from acute infectious diseases and in jaundice. Extrasystoles are present in children as a result of nervous irritability. Heart block and pulsus alternans are uncommon. Dilatation of the heart due to a loss of cardiac tonicity is not infrequent in children, and on percussion may be mistaken for a sign of endocardial or myocardial disease. Functional murmurs are common in children. The exact origin of such murmurs is not well known, but an atonic condition of the heart is probably the underlying cause in the majority of cases. The term, functional murmur, as commonly used to indicate that a certain murmur is not organic or valvular, does not mean anything. In order that a murmur may be called functional it must be assumed that it is caused by an abnormality of a certain cardiac function. Loss of that cardiac function called tonicity will give rise to cardiac atony, dilatation, and murmurs which may then be called functional or atonic murmurs. These murmurs are inconstant, soft, and short, limited in area of transmission, and systolic in time. There is usually no history of rheumatic infection, but there is evidence of malnutrition, anemia, or neuropathy. A functional or atonic murmur should never be considered as a sign of any local or systemic disease. It has no diagnostic value

beyond the fact that it indicates a general loss of muscle tone in which the cardiac muscle shares. The organic murmurs are persistent under all conditions of rest and exercise, loud, harsh, well conducted, and either systolic or diastolic. There is usually a history of rheumatic or other infection. The congenital murmurs are present during infancy and early childhood. They frequently have no exact relation to the normal sounds of the heart and are loud and rasping. The right side of the heart is usually enlarged, and there may be general cyanosis and clubbing of the fingers.

While a murmur may be a sign of heart disease, it may also be present in a heart of normal structure, and the absence of a murmur does not indicate a normal heart. A murmur in itself is of no significance, except in relation to the general condition of the patient, the size of the heart, the character of the normal heart sounds, and the condition of the pulse. The most important sign and symptom of cardiac health is its functional capacity as a working organ to carry on a normal circulation under conditions of rest and exercise.

In the adult, abnormalities of function are usually part of abnormalities of structure, while in the child a number of functional abnormalities may be present without structural changes, but due to an as yet unstable nervous system and lack of nervous control. Since functional cardiac disorders are common in children, and may give rise to the same abnormalities which are present in structural cardiac diseases, including dilatation and murmurs, it is of the utmost importance correctly to differentiate structural disorders due to anatomical changes from functional disorders due to imperfect nervous control and balance.

GRAVES'S DISEASE.

A Case with Postoperative Amblyopia.

By Chester Henry Keogh, B. A., M. D.,
Chicago.

Case. In 1914, S. M., aged forty years, single, American, came under my observation. The following signs were present: Bilateral exophthalmos; enlarged thyroid gland; tachycardia, pulse about 130; marked tremor; dyspnea; dyscrasia. The patient complained of insomnia, and "extreme nervousness." Diagnosis: Graves's disease.

As at that time surgeons generally were insisting that all cases of goitre, including the exophthalmic variety, were properly surgical cases, and as the patient was then easily able "to walk around the block," an equivalent of four city squares, without excessive fatigue, a surgeon was consulted. After a reasonable period of rest in bed by the patient, a partial thyroidectomy was performed in October, 1914.

The results of that operation were not satisfactory to the patient, so without consulting the operator, and without my knowledge, she went to another surgeon, who performed a second operation upon that portion of the thyroid gland remaining, May, 1915. A psychosis, emotional instability, nausea, vomiting, severe headaches, and blindness immediately followed the second operation.

Quite recently the patient came again under my observation. Emotional instability had then practically disappeared, as had also the nausea and headaches. Nor was there longer in evidence goitre, tremor, or extreme tachycardia, though the pulse frequently then observed was about 104, and so continued. She complained of weakness and partial blindness. As she described her disability, "everything seemed hazy."

Surgeons have called attention to the frequent sympathetic or synchronous association of disordered hypophysis and thyroid gland, and with a thought of finding, perhaps, the hypophysis a cause of the blindness, the patient was sent to an x ray laboratory. Four skiagraphs, anterior, posterior, right and left lateral exposures, revealed nothing abnormal, except possibly a bending slightly forward of the right posterior clinoid process.

An ophthalmologist reported these findings: 1. Atrophy of the optic nerves. 2. Marked contracture of the fields of vision in both eyes; color fields contracted. A perimetric chart was made of the condition. 3. No evidence of existing choked disc or other signs of intracranial pressure.

Further observation of the patient provided the following data: Carbohydrate tolerance; levulose was given on several occasions, 100 grams, 110 grams, 125 grams, 150 grams. No trace of sugar was detected in the urine. Examination of feces showed no sugar. Temperature, 99.6° F. Blood pressure, 130 systolic. Pulse, 104. Weight, 140 pounds.

Of hyperpituitarism in this case, there is not the slightest evidence. Of hypopituitarism, it has been repeatedly pointed out that, while increased tolerance for carbohydrates may be a measure of hypophyseal gland activity, in hypopituitarism there has been noted, in addition, usually: 1. Lowered systolic blood pressure. 2. Slow pulse. 3. Temperature below 98.6° F. 4. Increasing weight of patient. Of hyperthyroidism, there is now no evidence, though it is interesting to note that Geyelin has recently pointed out a lowered carbohydrate tolerance in twenty-seven cases of hyperthyroidism.

Of hypothyroidism, or myxedema, many observers have pointed out the increased tolerance for carbohydrates, as in this patient, while Dr. J. G. Kiernan has repeatedly observed in purely nervous disorders increased as well as diminished tolerance for carbohydrates in certain unstable individuals. In this case the contracted fields of vision and the scotomata for color might be explained by the condition of simple emotional instability, were it not for the findings of the ophthalmologist, who pointed out the bilateral atrophy of the optic nerves; though, whether the atrophy is primary or secondary, he declines to express an opinion.

One competent observer, in his cases of hypopituitarism, has repeatedly referred to the presence of primary atrophy of both optic nerves, and in some of his cases in which primary optic atrophy was present, operation upon the hypophysis resulted in restoration or improvement of vision.

The optic nerves could not then have been really atrophied, or subsequent regeneration of these nerves must be accepted. Of the latter alternative it has been noted in toxic amblyopia from drinking methylated spirit, improvement in vision followed treatment by the ophthalmologist when optic nerve atrophy had been the accepted diagnosis.

From the foregoing premises, what reason is there to think that in the case of this patient, too, the vision may not have been affected by some form of very severe toxemia?

Intestinal toxemia has not been excluded as an etiological factor in disorders of the thyroid, and why may we not logically assume that most of the phases of the clinical picture in this case may be explained by the existence of some as yet definitely undetermined form of intestinal toxemia?

4346 Drexel Boulevard.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXIII.—How do you perform circumcision? (Closed.)

CLXXIV.—How do you treat ivy poisoning? (Answers due not later than September 15th.)

CLXV.—How do you treat furunculosis? (Answers due not later than October 16th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXII has been awarded to Dr. J. Otis Carrington, of Malden, Mass., whose paper appears below.

PRIZE QUESTION NO. CLXXII.

THE RESUSCITATION OF PERSONS APPARENTLY DROWNED.

By J. OTIS CARRINGTON, M. D.,
Malden, Mass.

Keep all crowds away to allow as much air as possible. Loosen, or better, remove all clothing or constrictions about the neck, chest, and waist, and try to rid the air passages of any water, mud, or mucus present. Clear the mouth of any foreign bodies like false teeth, etc., and see that the nares are not occluded. Pull the tongue forward and fix it there by passing a band around under the chin. Then turn the patient over, face downward, with a roll of clothing under the abdomen. By making firm pressure upon the loins, water from the lungs or stomach will be expelled. If the patient does not breathe after repeated efforts of this kind, resort to artificial respiration.

The pulmotor or lung motor should be the first thought as a means to resuscitate a person apparently drowned, and every effort should be made to obtain one. It should be used diligently and persistently until respiration becomes established. Oxygen should be used in conjunction, when available.

When means for mechanical resuscitation is not at hand, waste no time in waiting for its arrival, as every minute counts. Proceed at once with artificial respiration.

Schäfer's method. Place the patient on his abdomen with his face turned to one side and his tongue fastened to prevent choking. The physician then kneels at one side of or astride the patient, and placing his hands on the floating ribs so that the heel rests at about the posterior axillary line, presses upon the thoracic walls. This drives out any air in the chest and any fluid or mucus which may obstruct the upper air passages (expiration). Pressure is then removed and the natural elasticity of the chest wall causes inspiration. Repeat the movements about sixteen times a minute.

Sylvester method. Lay the patient on a hard or flat surface, kneeling behind his head. Grasp the arms at the elbows, bringing them upward and outward, so that they follow the plane on which the body is extended. This movement causes expansion of the chest or inspiration. After a moment's pause the arms are lifted toward each other, and then, while still approximated, are pushed down upon the floating ribs, upon which they are pressed. This drives the air out of the chest—expiration. Repeat these movements about sixteen times a minute. In this method the patient lies prone, the tongue is held to one side of the mouth and protruding, and a roll of clothing is placed beneath the shoulders.

Laborde's method is rhythmic traction of the tongue. Grasp the tongue with forceps and pull it well forward and upward from ten to fourteen times a minute until voluntary respirations occur. Such a movement causes the sensory nerves of the tongue to carry impulses to the phrenic nerve, which in turn causes the diaphragm to contract. This method is very successful and is most worthy of trial. When one tires physically of the Schäfer or Sylvester method, in the interim employ Laborde's method. It saves time and may bring success.

Artificial rhythmic compression of the heart, in addition to the various methods of artificial respiration, is a great help.

Never give up a patient so long as there is the faintest cardiac action. Pulsation may be obtained by deep pressure over the abdominal aorta just below the ensiform cartilage when it cannot be obtained elsewhere.

When breathing has become established, carefully remove all wet clothing and rub the body thoroughly dry. Wrap the patient in dry, warm blankets with heat to the extremities and restore circulation by friction to the limbs. When the patient is able to swallow, give small quantities of hot coffee, whiskey, or brandy as stimulants. Keep in bed, in a quiet, well ventilated, cheerful room, avoiding too many visitors for a while, and give a nutritious diet and tonics.

Dr. L. K. Hirshberg, of Baltimore, observes:

In fifty-seven water accidents between June 1 and July 1, 1916, in and around New York, forty-nine persons were drowned and only eight were resuscitated. Proper treatment and aftercare would have saved several of the others, and compulsory swimming lessons in childhood would have perhaps saved nearly all. Prevention and preparedness, however, are commonly absent.

Universal and compulsory swimming lessons for

all school children, universal training in the prone pressure, manual method of artificial respiration for all grown ups, will in the first instance prevent drowning, and in the latter accomplish more for resuscitation from drowning and other kinds of asphyxiation than is possible by any kind of lung motors, pulmotors, or other mechanical apparatus. Professor Yandell Henderson, head of the department of physiology of Yale University, vouches for this.

Nevertheless, while this is true as a universal method of training for drowning emergencies, artificial respiration with apparatus of a mechanical type surpasses the manual method in that the device is able to furnish the normal volume of pulmonary air, while the hands are not thus capable. Be this as it may, the quick and immediate application of a poor method is better than the delay of two or more minutes necessary at times for a perfect mechanical contrivance, such as the pulmotor or lung motor. The very fact that these devices are available and only five minutes away has resulted in the neglect of hasty and helpful hand pressure respiration. The mechanical devices, therefore, should never be farther than two minutes away from possible drowning accidents. Moreover, since all that any kind of a mechanical aid yet invented affords is artificial respiration with air rich in oxygen, it should be so simple as to produce no undue expectations of efficiency or magic. Physicians as much as nonmedical laymen are given to exaggerate what can be accomplished with these devices.

When the victim is taken from the water, not a second's delay, much less a minute or more, should be allowed to elapse before the prone pressure method is applied. To carry the nearly drowned or supposedly drowned person for some distance on shore or to a temporary hospital, instead of treating him at once, is perhaps to take away his life. Men or animals fished out of water in a drowning condition often have the heart still beating. If this is so and respiration has ceased from the waterlogged condition of the lungs, there is even a better chance of restoring the victim than if the heart has stopped. Even the latter contingency, however, does not present a hopeless problem. The first point is to work against time. This gives the operator the aid of the muscles of the body before they begin to lose their tone and elasticity. After five or ten minutes the tone of the chest and abdominal muscles is very low.

The Sylvester method supplies artificial respiration sufficient to keep the heart beating for twelve minutes, whereas the Schäfer method surpasses this by six to nineteen minutes. The heart will beat from eighteen to thirty-one minutes. Each fraction of a minute which elapses after respiration has ceased in drowning, reduces the chance of restoration by just so much. Beyond ten minutes, according to Professor Meltzer of the Rockefeller Institute and the resuscitation commission, restoration is practically impossible.

The Sylvester method demands that all rough usage be avoided. If respiration has not ceased, irritate the nostrils with pepper or snuff, or even tickle the nose. Splash cold and hot water alternately on the chest and back. If there is no respiration or other sign of life, lay the victim on his back, while one person loosens all clothing. The operator takes his place at the head, with another at his side. The victim is turned then face downward and one or two sharp blows are struck over the shoulder blades. Now the mouth, throat, and nostrils are cleaned of mucus, dirt, and water with a handkerchief, and the patient is turned again on his back, and his tongue is pulled forward and tied to the jaw, so that it will not fall back. All this is to be done quickly, in a few seconds of time. A roll of clothing or a pillow is placed under his shoulder blades, and the operator grasps the arms below the elbows, and draws them upward and outward above the head until they are fully on a line with the body. Held here one second, they are moved back again and pressed firmly against the side and front of the chest for another second. This imitates natural breathing, to wit, about fifteen movements to the minute. Friction of the skin over the legs, arms, and body, toward the heart, is simultaneously carried out and is part of the aftercare. The powers of swallowing are tested by a teaspoonful of warm water and, once established, wine, brandy, soup, and coffee are administered. Sleep is encouraged after the patient is in bed. Hot flannels to the stomach and hot water to the armpits, soles of the feet, and thighs are also helpful.

The Schäfer method is superior to the Sylvester method. The patient is put face downward on the ground and the lifesaver places himself on his knees astride the victim. He places his hands flat over the lowest ribs on each side and then steadily throws the weight of his own body forward on to the ribs in order to cause firm pressure, which must, of course, be gentle and not too powerful upon the victim's chest. In this way water is driven out of the lungs. At once, when it is accomplished, the operator lifts his body slowly away from the ribs to relieve the pressure, but he does not take the flat of his hands from the ribs. The upward and downward motion is repeated each five seconds. In fine, the swaying slowly up and down of the life saver occurs from twelve to fifteen times a minute. This is to be continued for at least a half hour, or until natural respiration returns. While one is doing this, others should be preparing hot flannels, hot water bottles, hot bricks and rubbing of the skin. Professor Schäfer admonishes *against* removing wet clothing or administering restoratives by the mouth until normal breathing has returned. Obviously, the Schäfer method, both in its immediate treatment and in the aftercare, is more certain and should be practised on drowned animals by every one. Nowadays, there is no excuse for either drowning or ignorance of methods.

Dr. Charles C. Henin, of Springfield, Mass., writes:

The treatment of an apparently drowned person consists in removal from the water, freeing the mouth and nostrils, removing foreign bodies, loosening clothing that binds the neck, chest, or waist, squeezing water out of the lungs and stomach with the body partly inverted, and cleansing the base of the tongue from the larynx, either by pressing for-

ward the angles of the jaw or by drawing the tongue forward out of the mouth. The body may then be laid out flat on the back, with a shawl, folded blanket, coat, or block of wood high under the shoulders so as to cause the front of the neck to be put on the stretch.

Now artificial respiration may be tried, and warm blankets, hot bottles or bricks and necessary medicines sent for in the meantime. The simplest way to perform artificial respiration is for the operator to place himself on his knees above the head, seize the arms near the elbows, and sweep them around horizontally away from the body and over the head until they meet above it, when a steady, strong pull may be made upon them for about three seconds. The arms may then be returned to the position alongside the chest and strong pressure now made against the lower ribs for several seconds. These movements should be made at a rate of about sixteen to the minute, should be maintained for one half to three quarters of an hour, and abandoned only when the heart has ceased to beat. Deep pressure just below the end of the breast bone may reveal pulsations in the aorta when they cannot be found elsewhere. As natural respiration begins, the artificial respiration should be timed to it. Ammonia or smelling salts may stimulate it or hot water may be dashed on the chest. Continued rubbing of the body and limbs toward the heart will aid the circulation and produce warmth. Hot bottles, plates, bricks, stones, or even boards will help to give warmth to the body. Twenty to thirty minims of ether may be given hypodermically. As soon as it can be swallowed, teaspoonful doses of brandy or whisky in a tablespoonful of hot water may be given every minute until danger is passed. Use the pulmometer if it is at hand. Weak tea or coffee, or beef tea, should be given after consciousness has returned. Removal requires great care, the head being kept low and respiration constantly watched.

Contemporary Comment

Needless Pets.—Dogs, cats, rats, and mice are the mediums through which much disease is scattered. People are constantly making war on rats and mice from economic necessity, is the timely comment of the *Texas Medical Journal* for August, but they seldom think of them as disease carriers and germ spreaders. There is no possible good that can come from rats and mice. It is more expensive to maintain a few of them about a place than to feed another person, aside from the harm they do in spreading sickness. They should be exterminated even by National, State and municipal action, if that is necessary. New Orleans and some other cities are endeavoring to do this for two reasons: that they are expensive to maintain and that they are responsible for some of the public scourges. The time will come when a city will be ashamed to admit that it has rats or mice in it.

But what about the dogs and cats? They are even worse than the rats and mice, for they are the favorite household pets of the country. They not only have free access to many homes, but are taken into the arms of the women and children of the family, and fondled and caressed, often when they are loaded with disease germs. Dogs and cats are inordinately filthy. Nothing is too dirty for them to get into with their feet and mouths; no place terrifies them because of the diseases that may be lurking there. They delight to roam about questionable places, especially at night, and expect to receive their customary caresses the next day. They are expensive to feed and dangerous to have around. Why will sensible people keep them? This may be regarded as a subject foreign to the scope of a medical journal, but it is written in the hope that the physicians of the country may interest themselves in exterminating these useless household pests.

Prevention of Anterior Poliomyelitis in Indiana.—Dr. J. N. Hurty, secretary of the Indiana State Board of Health, has announced that printed circulars and letters dealing with the prevention of infantile paralysis had been sent to about 600 health officers in Indiana, observes the *Lancet-Clinic* for August 19. The letter, in part, says: "In face of this danger every physician should inform himself in regard to infantile paralysis and in making diagnoses should make a special study of each case, having the disease in view. Advise your people to give special attention to preserving the health of the children. Daily bathing, plenty of fresh air, plain food, exercise and play, plenty of sleep, attention to the bowels; all these make for prevention."

Vital Statistics.—In spite of the almost universal recognition that the registration of vital statistics is imperatively necessary, this country has no reason to be proud of its record in the collection of such data. European countries have kept far more complete and accurate records of births, deaths, marriages, and diseases. The *Lancet-Clinic* (August 19, 1916) asserts that one reason for this has been the pioneer conditions that obtained as civilization marched westward. But now no such excuse is acceptable.

As aids in sanitation and hygiene, the collection of vital statistics is a duty of government no less important than the far less neglected function of collecting taxes. Dr. Cressy L. Wilbur, director of Vital Statistics of the New York State Department of Health, aptly says:

> As people come into closer contact in our crowded communities, vital records are of increasing importance to protect the rights and insure the privileges of the individual. Schools are overcrowded; child labor must be prevented; widows with minor children receive pensions from the State—perhaps old age pensions are coming; in a multitude of ways the State is entering into the daily life of the people and requiring records of births and marriages and deaths for the interest of the individual.

The American Medical Association might well devote some of its surplus energy to agitating for an enlarged vital registration area in these United States, and each individual member, in addition, might well support the sanitary administration of his community by making prompt returns to the officials in charge. Possibly within a decade European countries would not then be so far in advance of us in the keeping of trustworthy records.

EFFECTIVE SEWAGE DISPOSAL.

Like the poor we have the sewage disposal problem always with us, at all events in the neighborhood of New York. The condition of the Passaic River, for instance, is a long standing disgrace to a civilized community. It was told not long since in one of the daily journals that two men, escaped from a prison, in order to get away had to swim this notorious stream. They began to swim, but had not gone far when they were overcome by the foulness of the water, returned, and gave themselves up, saying they preferred a long term of imprisonment to such a fearful ordeal. But the Passaic River is by no means the only example of the indifference with which the question of sewerage is regarded by the health authorities and the inhabitants of many towns in the vicinity of New York. Moreover, Manhattan itself has been aptly defined as an island completely surrounded by sewage, and yet public interest has not been awakened to the vile and dangerous contamination of its rivers and harbor.

There are within easy reach of this city several conspicuous concrete examples of the carelessness and ignorance of the citizens and of seeming disregard for the public health on the part of the authorities. In many of what may not inaptly be termed suburban towns of New York, containing populations of ten thousand and upward, there are still hundreds of old fashioned privy middens. It is obvious that these are a constant menace to the health of the public at large, beside being an anachronism in a country which prides itself upon being up to date in all that relates to the material well being of its inhabitants.

The privy is dangerous for more than one reason. As it is cleaned out only at intervals, the soil around, especially if porous, becomes permeated with possibly infected excreta. In some instances, the water supply may become infected and if vegetables are grown in the neighborhood, these may also be infected. More than one epidemic of typhoid fever has been traced to vegetables infected in this way. A more likely means of the open privy becoming a source of infection is by the agency of flies. It is now freely recognized that the fly is a factor of supreme importance in the conveyance of disease, and the privy affords it unequalled opportunities for the display of its sinister powers.

The question may be asked, how does it happen that in progressive American towns, such relics of the dark ages are allowed to exist? The answer is, that in many towns sewage systems are in the hands of individuals, who manage them for profit and not in the interests of the health or comfort of their neighbors. From every point of view this is obviously a short sighted policy, but where gain is in question man is frequently blind. From every conceivable standpoint then, from that especially of decency and health, the privy should be abolished by law, that is, where facilities exist for a water carriage system which is after all the cheapest, cleanest, and most convenient, but requires careful management for its success. Municipal ownership of the sewage system is indicated in fair sized towns and, in any event, the open privy should be interdicted as a distinct menace to health as well as a slur on the good name of any self respecting community.

It has been suggested that where a water carriage system of sewage is not available, the dry earth closet should be substituted for the privy midden. This system is vastly superior to the privy in that it is neither an offense to the sense of smell nor apparently a detriment to health, but there are difficulties in the way of carrying out this plan, and it does not remove the chief objection to privies, that is, the retention of excreta in the neighborhood of houses.

In the case of towns in the environs of New York

where water carriage with proper sewage filtration is easily obtainable there is no excuse for the existence of devices for getting rid of excreta so crude and objectionable. It is curious, but true, that America with all her boasted advances, lags far behind Europe in many matters relating to sanitation and health.

The need in this country is to educate the people with regard to sanitation, to teach them that the occurrence of typhoid fever is a crime because it is preventable and that typhoid fever and other preventable infectious diseases will continue to take heavy toll of the population so long as the ordinary citizen is ignorant of the simplest essentials of good sanitation. Arouse the public to a sense of the danger of neglecting proper sanitation and instil into the minds of all citizens their responsibility in allowing epidemics to rage and they will insist that known and effective precautionary measures be enforced.

WAS TOOTHACHE THE CAUSE OF THE REVOCATION OF THE EDICT OF NANTES?

The revocation of the Edict of Nantes, which meant the abjuration of Protestantism by the Huguenots, was signed by Louis XIV, October 17, 1685. All Protestant conventicles in France were, by this document, ordered to be immediately demolished, and the Protestants were prohibited from assembling anywhere for the exercise of their mode of worship on pain of forfeiture of life and goods. Louis XIV had long felt some scruples with regard to the violation of the engagements of his grandfather, Henry IV, as consecrated in the celebrated Edict of Nantes, but in a secret consultation with some of his clergy he had been persuaded that he not only might, without injury to his conscience, revoke that great act, but that it was his duty to do so. When the two Colberts, Seignelai and Croissi, and even the young Dauphin, counseled delay, the King spoke in such a tone that all opposition was silenced. It was at this juncture that Croissi remarked that the King was suffering from toothache and had best be let alone.

Louis XIV, whose father died of consumption; who suffered from intestinal trouble in his youth; who was addicted to exhausting pleasures; who was perpetually exposed to all kinds of mental annoyance; and who certainly performed a large amount of hard work; happened, nevertheless, to live through the longest authentic reign ever recorded, namely, seventy-two years. His teeth were unsound, and, before middle age, all those in the upper jaw had been lost or reduced to scraggy stumps. As the king had a huge appetite, and could not masticate his food, he was subject to severe dyspepsia. Throughout the whole of the memorable year, 1685, he suffered from an inflammation of the upper jaw bone, following the extraction of a stump beneath which there existed an abscess. On one occasion his stumps gave him so much trouble that the royal dentist remained all day with his patient, and for the relief of the pain the actual cautery was used fourteen times. The great king had, in his toothache alone, quite enough to try his patience; and it is not astonishing that to this dental affliction may be attributed the evil state of mind which caused him to sign the revocation of the Edict of Nantes.

WANTED, A CONTROL.

If we were endowed with vision into the past we should be astounded at the immeasurable floods of fluid extracts and elixirs, at the mountains of powders and pills that trail off toward remote periods of time. Truly, if all but a minute portion of these were dumped into the ocean, as Oliver Wendell Holmes suggested, it would not only be worse for the fish, which would all be killed, but indeed we should have an ocean of drugs but little diluted by sea water. The variety as well as amount of these pharmaceutical products would be not only appalling but even pathetic to contemplate.

In the bacterial products, now made or in process of making, we are likely to have from present indications an equally startling exhibit and one likely to prove about as effectual, in comparison with its size, in the cure of disease. The foundation for the use of most of these new preparations is certainly more precarious than for most drugs, although we have, or ought to have, a more precise notion of what we are dealing with. Just as in the use of chemical curatives, however, because one or two persons recover from some ailment in the time in which we would expect them to recover no matter what the treatment, we are asked to believe that a certain serum or vaccine which was used is worthy of our purchase at no small cost, and of our abundant and confident use. We are startled at the evident ignorance, gullibility, or slavery to the use of something or other, displayed by the profession, for where there is smoke there is fire, and where bacterial products are marketed in such quantity they must be used by physicians.

The practitioner needs now, as he always has needed, a control for testing therapeutic means, reports, and advertisements of therapeutic agents, and that control must be his knowledge of the fundamental facts of medical science. He needs to keep in mind the expected behavior of the body in the given disease, and the expected behavior of the bac-

teria producing the disease; he ought to ignore the report of a few cases which "seem" to do well under a certain treatment, and he should always beware of the overenthusiasm which colors in rosy tints so many of our clinical reports.

Then we must not forget the mental effects wrought upon the patient by the use of a new agent, an effect which a remedy with which he is more familiar cannot possibly have. The results obtained by one person but not by another in the use of the same therapeutic agent often seem to be wholly mental and the result of common enthusiasm on the part of patient and physician.

At present—and they have had a fair trial—the results of the use of vaccines and serums in a general way is exceedingly disappointing, the more so because we expected so much from them. This fact serves to emphasize again the overwhelming value of prophylaxis, the fact that the body is usually fully equipped to meet disease, and that we must be cautious in our attempts to offer aid. We hope that bacterial products may be made more efficient in the future, but at present we need to be conservative and not allow the too enthusiastic to overcome our scientific sense of what is of real and not imaginary use.

THE SCHICK REACTION AND DIPHTHERIA CONTROL.

According to the New York city department of health (*Weekly Bulletin,* February 19, 1916), there was little reduction of the death rate from diphtheria after the marked fall which attended the introduction of antitoxin. Even with antitoxin diphtheria is twice as fatal as scarlet fever and three times as fatal as measles. It is a proved fact that if antitoxin is used in sufficient quantity on the first day of the disease, there is practically no mortality. Antitoxin is an equally effective preventive. The New York department of health therefore made the only tenable conclusion, that physicians do not treat diphtheria properly and promptly enough with antitoxin. Early diagnosis with early and adequate treatment on the one hand, combined with segregation of patients and suspects, will lead to a further reduction in diphtheria mortality as striking as that which followed the introduction of antitoxin. The lowering of the death rate with antitoxin marked a lessened mortality rather than a decreased case incidence.

The control of diphtheria has been greatly facilitated by the introduction of the Schick reaction as a specific test of immunity. The New York health department urged the use of this reaction on physicians as of prime necessity. Its particular advantages were discussed by Park and Zingher (*American Journal of Public Health,* May, 1916) who based their conclusions on the worth of the test when properly performed. They believed that a negative reaction after the age of two or three years indicated protection indefinitely against diphtheria.

The longer immunity conferred by injections of a toxin-antitoxin mixture, is best measured and controlled by the Schick reaction performed at intervals of one, three, six, and twelve months later, as a positive result shows that not sufficient antitoxin has been developed to inhibit the reaction. Park and Zingher emphasized the value of this reaction in establishing the diagnosis in cases which are doubtful clinically. It is sometimes difficult to decide whether a given case exists in a diphtheria carrier or is a beginning acute diphtheria. A negative Schick test excludes diphtheria, although a positive reaction is not conclusive for it. The authors illustrated this point by showing that a streptococcus tonsillitis in a diphtheria would be considered diphtheria from cultural examination alone, but that a negative Schick reaction here would show that there was no danger from the disease.

By use of the Schick test it has been shown that antitoxin administered intravenously up to six hours after absorption of the diphtheria toxin by the tissues, will partly neutralize the toxin and thus prove of benefit in late cases. This calls attention once more to the extreme importance of administering antitoxin before the toxin has been bound by the tissues, in other words, a few hours may make the difference between recovery and death. One special advantage of the Schick reaction is in determining persons among diphtheria contacts, especially in institutions and homes, who are susceptible to diphtheria. Park and Zingher advised the routine administration of 1,000 to 2,000 units of antitoxin to all contacts who give a positive Schick reaction.

The ability to determine accurately persons susceptible to diphtheria promises to stimulate interest in active immunization against it, and the authors cited above believe, apparently with good reason, that it will lessen and eventually eradicate the disease.

HEAVY DAMAGES FOR ILLICIT DRUG TRAFFIC.

A widow in the State of New York has secured a judgment against a firm of druggists because of the sale of heroine to her son, a boy about eighteen years of age. The jury allowed $2,000 compensatory damages and $1,000 punitive damages, according to *Public Health Reports* for June 16, 1916. In affirming the judgment, Judge Howard, of the New York Supreme Court, said: "During the time when these defendants were supplying this drug to the

young man he became a vagabond, an idler, a drug fiend, and a criminal, undutiful to his mother, worthless to himself, dangerous to the community. The jury was right in concluding that all this was the result of the illicit traffic carried on by these defendants, and that they should be punished for their reckless disregard of the rights and welfare of this boy and his mother."

The opinion is published in full on page 1563 of the *Reports*.

CAUTION IN USING IODINE ON THE ABDOMEN.

A. Ernest Maylard writes to the *British Medical Journal* for July 15, 1916, of the danger of using iodine to sterilize the skin before abdominal operations. Propping and Bertelsmann have reported in *Zentralblatt für Chirurgie* (19 and 26) the production of abundant fibrous agglutinations in dogs from the injection of a mixture of twenty drops of tincture of iodine in eighty c. c. of salt solution into the peritoneal cavity. Walker and Ferguson in the *Annals of Surgery* (February, 1916) reported the densest adhesions to be caused by touching the peritoneum lightly with a gauze pledget dipped in half strength iodine. Maylard states that carbolic lotion, one in forty, followed by the same, one in twenty, may well replace iodine in sterilizing the abdominal skin; strong alcohol is also excellent.

Obituary

ERNEST WATSON CUSHING, M.D., LL.D.,

of Boston.

Doctor Cushing died at his home in Roxbury on August 27th, in the seventieth year of his age. He was born in Boston and received his preliminary education at Chauncey Hall School. Subsequently he graduated from the academic department of Harvard University in 1867 and studied in the medical department until 1869, completing his professional studies at the College of Physicians and Surgeons, New York, in 1871. In 1894 he received the honorary degree of LL. D. from Tufts College. Doctor Cushing studied abroad after graduation, and was interested in the development of abdominal surgery due to Lister's discoveries. On his return to this country, he was one of the first to experiment with Koch's tuberculin. In 1887, he became editor of the *Annals of Gynecology and Pediatrics* and, in 1890, he translated Martin's *Diseases of Women*, applying the halftone process to photomicrography for the first time in the illustrations. He was one of the founders and for twenty years surgeon to the Massachusetts Woman's Hospital, and was professor of gynecology and abdominal surgery at Tufts College medical school from the day of its foundation until, some four years ago, when he was made professor emeritus. Among other accomplishments, Doctor Cushing counted familiarity with eight languages, the latest being modern Greek, which he had been studying for three years at the time of his death. He is survived by a widow and five daughters.

News Items

Yellow Fever on a Steamship.—Surgeon Corput, of the United States Public Health Service, reports that two patients suffering from yellow fever were taken off the Danish steamship *Borglum* three days out from Progreso, Mexico.

Personal.—Dr. Charles K. Mills, of Philadelphia, has been appointed consulting neurologist to the Philadelphia Hospital for Contagious Diseases.

Dr. C. D. Rilance, of Denver, who is a native of Canada, has gone to Quebec to join the Canadian army medical corps.

American Association of Obstetricians and Gynecologists.—The twenty-ninth annual meeting of this association will be held in Indianapolis, September 25th, 26th, and 27th, under the presidency of Dr. H. G. Pantzer, of that city. Dr. E. Gustav Zinke, of Cincinnati, is secretary, and will be glad to furnish further information regarding the meeting to all who are interested.

American Association for Clinical Research.—The eighth annual meeting of this association will be held in New York, September 28th, 29th, and 30th, with headquarters at the Hotel Majestic. There will be three sessions each day, morning, afternoon, and evening. Clinics will be held at the Flower, Metropolitan, and other hospitals. Dr. Daniel E. S. Coleman, of New York, is president of the society, and Dr. James Krauss, 419 Boylston Street, Boston, is permanent secretary and will be glad to furnish further information regarding the meeting.

High Death Rate in Poliomyelitis Epidemic.—The health department reports that the death rate of infantile paralysis has almost doubled during the past seven weeks, and is now greater than that of any other outbreak of the disease of which there is any record. During the week ending August 29th the rate was 31 per cent., and the average rate for the entire epidemic up to the morning of August 30th was 23.89. The weekly death rate during July and August was as follows: Week ending July 11th, 18 per cent.; July 18th, 16 per cent.; July 25th, 27 per cent.; August 1st, 23 per cent.; August 8th, 23 per cent.; August 15th, 23 per cent.; August 22d, 27 per cent.; August 29th, 31 per cent. The epidemic which occurred in New York in 1907 had an average death rate of 10 per cent.

The Aftercare of Infantile Paralysis Patients.—The health department has formed a Committee on Aftercare, composed of trained social service workers, to look after the welfare of the convalescent poliomyelitis patients. With the termination of quarantine at home, or with the discharge of a patient from the hospital, a printed notification is handed to the parents, pointing out the importance of proper aftercare. One side of this printed slip contains information for the parents and on the other side is a list of orthopedic hospitals and dispensaries in the city, together with the consultation hours. Where braces or other forms of apparatus are required and cannot be supplied by the family, they are furnished by the committee, a fund for the purpose having been contributed by citizens. Dr. Donald E. Baxter, 289 Fourth Avenue, is director of the committee.

Poliomyelitis in Adults.—The department of health has tabulated in age groups the ninety-four persons over sixteen years of age who are in the hospitals or quarantined at home with poliomyelitis. By boroughs they are as follows:

Manhattan: Women—One 23 years old, four 17, two 19, two 28, one 26, two 32, one 33, two 35, one 36, one 37. Men—Two 17, one 19, one 20, one 21, two 22, one 23, two 24, one 25, two 26, two 27, one 28, one 29, one 30, one 31, one 37, one 38, one 42.

Brooklyn: Women—Two 16, three 17, one 19, one 21, three 22, one 23, one 25, one 26, two 28, one 29, one 30, one 32, one 37, one 40. Men—One 17, three 18, one 21, one 24, one 25, two 26, one 27, one 29, one 30, one 32, one 34, one 37, one 46, one 52.

The Bronx: Women—One 19, one 20. Men—One 20, one 26, one 32, one 35.

Queens: Women—One 16, one 22, one 29. Men—One 25, one 35, one 46.

Richmond: Women—One 25, one 30. Men—One 17.

The death rate among adults is much higher than that for children, being about 40 per cent.

Compulsory Vaccination of School Children.—The Board of Health of Jefferson County, Kentucky, recently issued an order requiring that all children attending schools in School District No. 46, Highland Park, Ky., must be vaccinated, excepting such children as had been successfully vaccinated within seven years. The board of trustees of the school district resisted the enforcement of the order, but the Court of Appeals of Kentucky decided that the board was authorized by the Kentucky laws to take the action, and that the order must be complied with. The opinion is published in the August 11th issue of *Public Health Reports*.

Work of the Health Department in the Diagnosis of Venereal Diseases.—The work done by the diagnosis laboratory of the Department of Health of the city of New York in the examination of specimens from cases of suspected venereal infection, during the first quarter of the year 1916, is shown by the following figures, compiled by the department: Syphilis (complement fixation test), 13,419 specimens examined, 3,730 positive, 8,042 negative, 1,112 doubtful, and 535 received but not examined; gonorrhea (complement fixation test), 2,711 specimens examined, 248 positive, 1,841 negative, 281 doubtful, and 341 received but not examined; gonococcus (microscopical), 2,055 specimens examined, 321 positive, 1,220 negative, 410 doubtful, and 104 received but not examined; treponema (microscopical), 6 specimens examined, one positive, and 5 negative. The large proportion of negative reports indicates that physicians are making considerable use in diagnosis of the laboratory facilities of the department.

Domestic Animals and Poliomyelitis.—In order that exact information may be obtained whether poliomyelitis occurs in domestic animals, and if so, whether the latter play any part in the transmission of the disease, all the nurses in the health department now visiting cases of poliomyelitis have been instructed to make a special inquiry regarding animals. If they find anything suspicious they will report the matter immediately and the suspected animals will be removed by the department of health for observation. A veterinarian will be sent to examine the animal and if the suspicion is justified, the animal will be killed and an anatomical examination made. In addition, arrangements have been made whereby a veterinarian of the department will visit the shelter of the Society for the Prevention of Cruelty to Animals to see whether any suspected cases of animal infection are there encountered. In this investigation the Bureau of Preventable Disease will have the cooperation of the Bureau of Laboratories and of the United States Public Health Service.

Michigan State Medical Society.—The fifty-first annual meeting of this society was held in Houghton, Mich., August 15th, 16th, and 17th, under the presidency of Dr. A. W. Hornbogen, of Marquette. The meeting was well attended and was said to be the best in every way that the society had held for twenty years. An interesting feature of the meeting was the passing of resolutions recommending universal military training and requesting the Michigan congressional delegation to exert itself to bring about effective legislation to this end. The society also adopted the report of the committee recommending the passage of a State eugenic law requiring that every applicant for a marriage license shall submit to a medical examination before marriage. Dr. Andrew F. Biddle, of Detroit, was elected president, and other officers were elected as follows: First vice-president, Dr. J. G. Turner, of Houghton; second vice-president, Dr. J. J. Mersen, of Holland; third vice-president, Dr. O. A. Hart, of St. Johns; fourth vice-president, Dr. J. A. Nye, of Port Huron. The house of delegates conferred the following honorary memberships: Nonresident, Dr. F. M. Albee, of New York; resident, Dr. W. A. Whitney, of Big Rapids; Dr. George W. Jones, of Inlay City, and Dr. William Blake, of Lapeer. Nonresident honorary memberships are conferred on members of the society who by reason of age are about to retire from active practice. The delegates approved resolutions, later to be prepared by Doctor McMillan, of Detroit, on the death of Dr. John B. Murphy, of Chicago, an honorary member of the society.

Prevalence of Communicable Diseases in the United States.—The United States Public Health Service has published a series of tables showing the prevalence during the year 1915 in cities of the United States with a population of over 100,000 of the following diseases: Diphtheria, gonorrhea, malaria, measles, epidemic cerebrospinal meningitis, pellagra, poliomyelitis, rabies in men, rabies in animals, scarlet fever, smallpox, syphilis, tuberculosis, and typhoid fever. These tables have been compiled from data obtained from the health departments of the respective cities. They include the number of cases reported, indicated case rates in a thousand of population, and indicated fatality rates in one hundred cases. The pamphlet is Reprint No. 347 from *Public Health Reports* and copies, at five cents each, may be obtained from the superintendent of documents, Government Printing Office, Washington, D. C.

A Conference on Poliomyelitis.—A conference of State and Territorial Health Authorities with the United States Public Health Service for the consideration of the prevention of the spread of poliomyelitis was held in Washington, D. C., August 17th and 18th. The conference was called to order by Surgeon General Blue, of the Public Health Service. The general poliomyelitis situation was presented, each delegate giving a brief statement of the situation in his State. The program included a discussion of the following topics: The prevention of the interstate spread of poliomyelitis, the research problems in poliomyelitis, symptomatology of poliomyelitis, epidemiology of poliomyelitis, general principles of control, and the relation of the community to the aftercare of poliomyelitis patients. The following committees were appointed and each committee made a report which was adopted by the conference: Committee on measures for the prevention of interstate and intrastate spread of poliomyelitis; committee on minimum requirements for the control of infantile paralysis; committee on blanks. A complete report of the transactions of the conference will be issued at an early date.

Opinion Rendered at the Request of the Medico-economic League on the Subject of Pay Clinics.—You state that you are informed that certain large charitable institutions of this city contemplate the establishment of night pay clinics for medical and surgical treatment of persons, on a general basis of one dollar a visit. This is a matter which may be considered when occasion arises. Unless facts are presented showing the character of the dispensary and the manner of fixing the charge and the disposition of such funds, it is impossible to pass upon the question. I have no hesitancy in stating, however, that a charge even of one dollar, if made in accordance with the provisions of Section 290 by a dispensary which fully complies with the standards, requirements, and purposes of Section 291 of the State Charities Law, would be lawful. Whether a person who pays one dollar for treatment at such a dispensary is a proper object of charity, depends entirely upon the circumstances in each individual case. If all that patient can afford to pay is one dollar, and he may obtain treatment by a specialist for that amount at a dispensary, while treatment by the same specialist at the patient's home or the physician's office would be entirely above his means, I do not see why such patient cannot avail himself of the services of such specialist. There are many physicians and specialists of great skill and high professional standing who give time to dispensaries to treat just such cases. It is their generous contribution to the general welfare of the community. The advantage of a dispensary is that the patient will there find a coordinated group of specialized physicians, surgeons, and pathologists, working together in a comprehensive organization. I see no danger of the use of dispensaries being abused by persons who can afford to pay the full quota of specialized surgical or medical treatment, for Section 296 of the State Charities Law provides that

> Any person who obtains medical or surgical treatment on false representations from any dispensary licensed under the provisions of this article, shall be guilty of a misdemeanor and on conviction thereof shall be punished by a fine of not less than ten dollars and not more than two hundred and fifty dollars.

I feel that dispensaries of the standard conducted by the institutions named should be encouraged.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE MANAGEMENT OF ENURESIS.*

By Harry Apfel, M. D.,
New York,
Instructor in Diseases of Children, New York Post-Graduate Medical School and Hospital.

The fact that wetting the bed could, in many instances, be attributed to the carelessness with which the child has been reared during the early months of its existence, does not forego the conclusion that a given case may not be due to a severe pathological condition, either in the urinary tract or nervous system, or in the chemical makeup of the urine. Some cases are of nocturnal type, others of diurnal type, occasionally the two types coexist.

No disorder in the whole category of child ailments is so persistent and so annoying as a protracted case of enuresis, and nothing is more gratifying to parents as well as to the physician as to have a case which has existed and persisted for months and years clear up under proper management. Here the word *management* should be emphasized, for we do not mean treatment by means of drugs exclusively, rather do we have in mind a proper régime as to diet, hygiene, etc.

Etiology. Under ordinary circumstances a child between two and three years of age has its inhibitory centres well enough developed to be able to control the bladder function. Obviously, this age limit is arbitrary; there are not a few exceptional children that have not wet themselves from the time they reached the first anniversary of their birth, a feat not to be credited so much to the cleverness of the child, as to the intelligence of the nurse or mother. One patient assured me that her baby had not wet the napkin since she was six months of age — an exceptional case, but possible. Here, as in other conditions in the field of causation, the simplest points will usually be overlooked unless a complete physical examination plus a most painstaking history is made at the very first visit. Next in order of importance is to get acquainted with the child's habits, as to taking water, tea, or coffee, at bedtime. The practice of taking the heaviest meal in the evening, when the older folks return from business, incidentally makes the child carry with it to bed an overloaded intestinal tract which is conducive to a desire to empty the bladder during the next two or three hours, when the child is sound asleep.

Constipation has long been recognized as a common factor; anemia and chlorosis also hold important places as causes. Pin worms are very frequently overlooked, unless the mother calls attention to the presence of small threadlike pieces that she has noticed while making child's toilet. A neurotic or hysterical child frequently suffers from enuresis: furthermore, epilepsy sometimes manifests itself by no other symptom than by attacks of wetting the bed at night. A urine loaded with urates or oxalates may account for the trouble; also a lesion of the central nervous system, i. e., idiocy, cerebral palsy, meningitis, tumor of the brain, forms of myelitis, and injuries to the cord, any one of which is a very unfortunate occurrence. Last but not least to be mentioned, and not infrequently overlooked, is an adherent clitoris in the female; or a long and narrow prepuce in boys; also a vesical calculus or cystitis, the last of which is very rare.

The management may be grouped under the following subdivisions: 1. Instructions to mother; 2, a diet list; 3, correct any existing pathological conditions; 4, endeavor to obtain the cooperation of the child; 5, drugs.

1. The mother should be told the proper time for the child's bath, play, exercise, and time of meals and time for going to bed and rising. Dwell somewhat on the importance of a properly ventilated room where the temperature should not exceed 65° F. The child should not be made too comfortable in its bed. The mother should be reminded to keep the child's bowels open daily. In a few words, explain to the mother the plan of your entire campaign and ask her for assistance.

2. We give to the mother a written diet list, specifying the hour for each meal, eliminating spicy food articles as well as tea and coffee. We should lay special emphasis on the point that the child receive no liquids after five p. m. If it is very thirsty, water by the teaspoonful only may be allowed. In highly acid urine, eliminate strongly acid fruits; limit pastry as well as red meats.

3. We start with the supposition that a physical examination has failed to reveal pathological lesions of the central nervous system, also that there is no adherent clitoris or long and narrow prepuce, or a vulvovaginitis or calculus in the bladder, and that the patient has not hypertrophied tonsils or adenoids; if any such condition does exist we should correct it if possible.

4. Next we direct our attention to the child himself and attempt to get his confidence and cooperation, which means everything if our treatment is to be a success. We give the child a vessel and ask him to urinate right in our presence, and at the word of command make him stop and then start again; in other words, we train the power of control of his bladder sphincter (Pisek). We tell the mother to repeat this with the child once a day. Then we give the child a blank sheet of paper, on which we note the days of week, and the little patient is asked to keep his own record by simply noting every morning *yes* or *no* alongside of the day. If too young to write, use an x under wet or dry, depending on whether he has been found wet or dry. This, we find, makes a great impression on the little patient's mind, especially if we offer a prize for a complete negative chart at the end of the month.

In older children, especially in obstinate cases, passing a cold sound may help a great deal when other methods fail.

*Read before the East New York Medical Society, May 5, 1916.

5. As to drugs: notice that we have left that part for the last, for we believe it of less importance than the things mentioned above. At any rate, the value of drugs has been greatly overestimated.

Of all drugs which were given a trial, atropine sulphate still holds first place for efficacy, *if used properly*. It is best given in an aqueous solution containing half a grain of the atropine sulphate to the ounce. Of this give drop doses for two days, t. i. d.; then increase to two, to three (Kerley), watching for dilated pupils and flushed cheeks, unless results are noted sooner.

In anemic children, iron, especially the albuminate, is recommended. In strongly acid urine, potassium citrate should be given.

If the urine contains colon bacilli, that should be corrected with hexamethylenamine. In extremely nervous children, especially those prone to attacks of petit mal, the bromides should be given in large doses.

A great deal of patience and perseverance is required by both patient and doctor, for in many cases the wetting stops, only to return as soon as we cease treatment. It is therefore well to continue treatment in every case for some time after an apparent cure has been brought about, in order that the patient may overcome the effect of habit, of which he may not always rid himself easily.

Thyroid extract and glandular therapy generally has been tried, but it is questionable how much good it does, except in cases of hypothyroidism. A patient I now have under treatment in our clinic came in for ichthyosis, from which she had been suffering since birth; upon examination she showed all symptoms of hypothyroidism plus enuresis. On thyroid treatment she promptly stopped wetting herself.

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirty-fifth Communication.

SCARLATINA.

Until a satisfactory serum shall be developed the principal lines of treatment in scarlet fever must be to ward off complications and to support the vital processes. In this endeavor less may be gained by drugs than by the persistent use of simple hygienic measures.

Middle ear complications are best prevented by frequent careful cleansing of the nasopharynx; for this purpose nothing excels normal saline solution rendered alkaline with borate or carbonate of sodium; the addition of traces of menthol or eucalyptus may be of some inhibitory value through a slight antiseptic effect, but simple home made solutions are fully as satisfactory as the various expensive ones on the market. Keeping the nasopharyngeal mucosa well cleansed is the best way of preventing extension of the inflammatory process into the Eustachian passages.

In controlling the fever great care must be exercised, inasmuch as cool applications may easily interfere with the normal development of the eruption. Bathing to reduce fever should be with water only a few degrees lower than the existing body temperature, and the process should be conducted in a room sufficiently warm to admit of no sense of chilliness to the patient. But for treatment of the nervous symptoms cooler applications, by means of the cold coil or even the ice bag, may be made to the head. Frequent bathing for purposes of cleanliness is also desirable to further skin activity in toxin elimination. The older idea of frequent inunctions to prevent dissemination of the desquamata may well be discarded as not conducive to cleanliness. The exfoliated scales are adequately removed in the bath, while evidence of the contagiousness of the scales is lacking, the theory of such means of propagation having been largely abandoned by modern investigators.

The use of some of the coal tar series for antipyresis may be mentioned to be condemned. There is ever present in scarlet fever a tendency to cardiac complications, and we can ill afford to increase it by giving any drug which has a direct toxic effect on the heart.

The tendency to irritation nephritis is best combatted by frequent stimulation of the eliminative function of the skin, by washing of the blood stream, by complete rest in bed, and by limitation of the diet to simple nourishing liquids. The skin is capable of rendering much assistance to the kidneys, and this potentiality should be fully utilized. Hot air, dry or moist, will accelerate perspiration; at the same time copious hot drinks must be taken, or resort made to full saline enemata, as it is essential that the specific gravity of the blood be not raised but rather lowered. The diet must be reduced to the minimum for present metabolic efficiency, and administered in a form calling for the least amount of digestive effort.

In robust children, in whom there is an unduly marked reaction of the heart, as shown by high pressure tension and by excessive rapidity of the pulse, the heart may be advantageously brought temporarily under aconite control, great care being taken that there is used only the minimum amount required to obtain the desired effect and that the ensuing reaction is carefully kept under observation. Powerful drugs should always be administered well diluted, and diligent discretion should be exercised.

In later stages of severe attacks, cardiac feebleness develops not infrequently; this may be treated symptomatically with caffeine for the sake of its stimulating effect on the heart, and with strychnine for its heightening of the sensory reflexes of the cord; but the physician must strive energetically at the same time to eliminate the causative toxemia.

Postscarlatinal anemia may require prolonged treatment with iron, in which case the old fashioned carbonate or the newer citrate constitutes the best preparations.

MEASLES.

With some slight exceptions the treatment of measles is nonmedicinal. The patient, being always extremely sensitive to light, should be kept in a darkened but well ventilated room. The same cleanly care should be taken of the skin as in cases

of scarlatina, but there is seldom need for special measures in temperature reduction. The nose and nasopharynx, however, need the same scrupulous care and attention as in scarlatina, frequent cleansing with alkaline solutions being a leading indication. The cough, if too troublesome, may be treated with steam inhalations medicated with oil of eucalyptus, or the oil may be dropped on a handkerchief and then inhaled. If the cough proves intractable to the foregoing treatment, resort may be had to a reflex depressor, such as codeine, exhibited in elixir of wild cherry; but the use of codeine should be sharply limited, both in amount and duration.

During convalescence, nourishment should be pushed, and the patient kept as much as possible in the open air, but amply protected from draughts.

Treatment of Septicemia.—Lorrain Smith and Ritchie (*West London Medical Journal,* July, 1916) report two cases treated by intravenous injections of eusol. Eusol is the name given to an aqueous solution of 0.5 per cent. strength of free hypochlorous acid, prepared by shaking twenty-five grams of a mixture of equal parts of chloride of lime and boric acid in a litre of water and then filtering. For intravenous injection, 8.5 grams of salt are added; 100 c. c. were administered in one case and 120 c. c. were administered in the other. The results were favorable, the temperature in one case falling from 160° to 96° in twelve hours.

Treatment of Cancer of the Uterus.—Donald C. Balfour (*Texas State Journal of Medicine,* July, 1916) advises early cauterization in early cancer of the uterus, followed immediately by a total abdominal hysterectomy. In a small percentage of the cases the condition of the patient may demand a vaginal hysterectomy as the wisest procedure. For moderately advanced cases the use of heat by the Percy method is best. From the results of this treatment the surgeon must decide whether a total abdominal hysterectomy is advisable and, if so, when. If the patient is a serious operative risk, vaginal hysterectomy should be considered. In advanced cases a determined effort should be made to ameliorate the symptoms and prolong life by heat, radium, etc. This treatment, at times, is rewarded by a result which permits radical operation.

Clinical Results with the Tungsten Lamp.—A. B. Cottell (*Brit. Med. Jour.*, July 29, 1916) reports that sinuses and indolent ulcers caused by frostbite, and other forms of resistant lesions have invariably responded favorably to treatment by the tungsten lamp. They have healed much more rapidly than under other methods of treatment, and the scar left was soft and closely resembled the normal skin. Lupus and other forms of tuberculous ulceration also healed quickly and with soft scars. The same was true of a phagedenic ulcer. Other conditions were also benefited, such as asthma and some forms of stiff joints. The first exposure to the light should be for only one minute, which can be increased later to from two to five minutes depending upon the local reaction. No subsequent exposure should be given until the reaction from the previous one has passed off. The eyes of both patient and operator must be shielded from the rays.

Treatment of Simple Prurigo.—P. G. Unna (*Berlin. klin. Woch.,* Feb. 14, 1916) reports that ichthyol acts both as a symptomatic remedy for the swelling, and as an etiological remedy against the causal infection. The most rapid results may be secured by first rubbing the affected area with sandpaper, and by following this with an application of an antipruritic and antiparasitic powder containing ten per cent. of paradichlorbenzol. This causes some temporary burning, but when this passes off the itching will have been relieved. Then a varnish containing ten per cent. of ichthyol in gelanth should be applied. [Gelanth is a water soluble varnish made from gelatin and tragacanth.] In obstinate and recurrent cases the addition of one or two per cent. of chrysarobin to the ichthyol varnish is very helpful, and the application of this should be preceded by a lathering of the parts with ichthyol soap.

Acidosis in Children.—J. M. Grantham (*Jour. Florida Med. Ass.,* July, 1916) considers that the alimentary tract should be thoroughly emptied by a dose of castor oil or by repeated doses of one-tenth of a grain of calomel until evacuation. The colon should also be irrigated. During the first day the food should be a seven per cent. solution of milk sugar and later a one per cent. barley water, to which milk sugar is added. If nausea or vomiting prevents the taking of food by mouth a five per cent. glucose solution may be given by rectum. Medicinal treatment consists in the administration of alkalies until the urine has become decidedly alkaline in reaction. For this purpose a saturated solution of sodium bicarbonate is the best, and of this a tablespoonful in some ice water may be the initial dose, to be repeated hourly day and night with an increase in the dose if the patient will stand it. In very severe cases one or two drams of a four per cent. sodium bicarbonate solution may be given intravenously and repeated as required.

Treatment of Carriers of Amebic Dysentery.—H. H. Dale (*Lancet,* July 29, 1916) describes a number of cases in which a course of the usual hypodermic emetine therapy produces only a temporary disappearance of cysts from the stools. Such cases relapse into chronic cyst carriers. The use of ipecacuanha by mouth seems to have given better results in this class of cases, but it is often impossible to give a thorough course of treatment in this way, owing to the production of nausea and vomiting. A double iodide of emetine and bismuth has been prepared recently and furnishes a salt from which the emetine is liberated only after passage into the alkaline intestinal fluids. Three grains of this salt represent one grain of emetine and are equivalent to sixty grains of ipecac. This preparation was tried by Dale in a small series of chronic carriers with strikingly favorable results. In the majority the cysts were promptly and permanently removed from the stools. In a few of the patients some nausea was observed, but this could often be prevented by administering the dose with, or immediately after a meal. The daily dose ranged from two to four grains administered in capsules. It is suggested that this new preparation might be employed in small doses repeated every few days as a prophylactic for those exposed to infection.

X Ray Treatment of Superficial Dermatoses.—E. Kuznitzky (*Berlin. klin. Woch.,* Feb. 14, 1916) comments upon the controversy which has been waged for some time between the advocates of large doses of filtered hard rays and of small doses of soft rays. A middle ground between the two can be taken, for the author has found that moderate doses of medium hard, filtered rays are entirely satisfactory and without danger. He uses a medium tube and a filter of one half mm. of aluminum. An initial dose of half an erythema dose is given, and at ten to fourteen day intervals two doses of one third erythema strength are administered. This plan of application has proved entirely successful in psoriasis, chronic infiltrated eczema, etc., and entirely avoids the dangers of erythema, burns, or epilation.

Note on Serum Treatment of Poliomyelitis.—Simon Flexner (*Journal A. M. A.,* August 19, 1916) states that experiments with powerful strains of the virus of this disease have shown that in monkeys the administration of immune serum will prevent or greatly delay the onset of artificial infection, or that if given soon after an inoculation of active virus will abort the disease. It has also been shown that the serum has marked curative properties in these animals. The use of immune serum in man was first tried by Netter in a short series of cases, with apparently good results. The experimental results would seem to indicate its value in man, and its use is worthy of an extended trial. Owing to the fact that the infection is chiefly localized in the spinal meninges, the serum should be given intradurally through lumbar puncture after the removal of some of the spinal fluid. The dose should probably range from five to twenty c. c., and the serum should be tested by the Wassermann reaction before use. It should be given as early in the course of the case as possible, and repeated daily if needed.

Suggestion as to the Prevention of Infantile Paralysis.—W. Stewart Whittemore (*Boston Medical and Surgical Journal,* August 17, 1916) was so impressed by a report made by Hektoen and Rappaport about a year ago on the use of kaolin to remove bacteria from the nose and throat that he began to use it on himself and on members of his own family in the treatment of coryza and tonsillitis, later on other patients, with good results. The method employed was to dust finely powdered kaolin into the nose six or seven times a day at two hour intervals by means of a powder blower, after the patient had cleared his nose by blowing it thoroughly. Hektoen and Rappaport found that in this way they were able to remove diphtheria bacilli, and practically all bacteria from the nasal mucous membrane in three or four days. By applications to the throats of diphtheria carriers, the bacilli were permanently removed in from two to four days. In scarlet fever the kaolin removed streptococci from the nose very promptly. Although we are still in great ignorance as to the mode of transmission of infantile paralysis, it is agreed that the most common avenue of infection is through the mucous membrane of the nose, so it seems logical in combating the disease to use a substance which has been shown to be capable of practically sterilizing the nose and throat, and is, moreover, free from any irritating effect. Far from being a chemical poison, it can be swallowed in large amounts without any poisonous effect upon the taker. Its action is peculiar in that it seems to owe its efficiency in bacterial infections to its action in depriving the bacteria of a suitable medium, while mechanically burying them alive. For these reasons the writer urges the use of kaolin as a prophylactic measure in the case of every child or adult who has come in contact with any possible source of infection of infantile paralysis, as it has been shown that healthy persons in whose households the disease occurs seem to be carriers. Kaolin should be used also by patients suffering from the disease, and by those who have recently recovered from it, because swabs taken from the nose have demonstrated the presence of the virus in such persons long after recovery.

Röntgen Treatment of Epithelioma.—John H. Edmondson (*American Journal of Röntgenology,* July, 1916) begins treating cutaneous malignancy with bipolar fulguration, cauterization or coagulation. This has a threefold effect: 1, The most superficial and a great number of deeper cells are destroyed; 2, it renders the field more accessible and amenable to treatment; 3, it closes metastatic channels. Immediately following this an exposure of about ten to twenty units of a No. 6 Benoist unfiltered ray is given to the neoplasm only; the next day a second exposure of four to five units from a No. 8 or a No. 9 Benoist, filtered through three mm. of aluminum. At this second exposure about one half inch of the surface immediately surrounding the growth is included. The patient is then dismissed until the reaction subsides. He is told to return for observation. If any manifestation of the condition remains, the same technic is repeated. If not, another exposure of about four units is given in order to destroy any unobserved manifestations.

Prevention of Deformities in the Healing of Burns.—Charles A. Parker (*Jour. A. M. A.,* August 19, 1916) states that however extensive they may be, in third degree burns so long as they are compatible with life, the healing should be secured without deformity and with the preservation of good function. It is chiefly in the burns about the neck and involving the extensor surfaces that difficulty is encountered in preventing deformity and loss of function, or its impairment. The burn itself should be regarded as an ulcer, and should be treated appropriately by skin grafting or other methods, the most satisfactory of which is the covering of the wound with overlapping strips of adhesive plaster which are allowed to remain *in situ* until they begin to separate from their attachments to the normal skin. This requires their renewal about twice weekly. Over the adhesive plaster dressing dry absorbent gauze should be applied, and this can be changed daily, or as the absorption of the secretions demands. This form of dressing constitutes essentially a wet dressing in which the moisture comes from the patient's own serum and lymph. Combined with this direct treatment of the burns themselves, the parts should be placed and main-

tained in a suitable position to prevent deformity. This is usually one of extension in the case of the joints of the extremities, of abduction when the burn is in the axillary region, and of elevation and rotation of the chin to the opposite side in burns of the neck. The position must be maintained by the application of suitable plaster splints which can be removed for the dressings and reapplied at once. These must be used continuously during the entire healing and for some time thereafter, and then may be left off during the day, but worn for some time longer during sleep. The persistent use of the night casts is essential for the complete prevention of deformity.

Feeding in Infancy.—F. P. Gengenbach (*Texas State Journal of Medicine,* July, 1916) concludes that mother's milk is the best food for an infant. If the mother's milk fails, or, if after a prolonged trial it does not agree with the child, a wet nurse is preferable. If a wet nurse cannot be obtained artificial feeding should be attempted. Whole milk mixtures are preferable because of their simplicity. Boiled milk is better borne than raw milk. The use of sodium citrate and of cereal diluents frequently proves helpful. Raw milk should be substituted gradually for boiled milk, and where an intolerance for raw milk exists other foods should be added to the dietary.

Marfan's Epigastric Puncture in Rheumatic Pericarditis with Effusion.—P. Lereboullet (*Paris médical,* July 1, 1916) deprecates the prevailing tendency to avoid paracentesis of the pericardium in rheumatic pericarditis. In some of the more severe cases this procedure is absolutely necessary to save life. He recommends Marfan's epigastric method, which has already proved satisfactory in cases of pericardial effusion due to tuberculous infection or Bright's disease. The Marfan procedure permits of exploring or evacuating the pericardium with less risk of injuring the heart muscle than in the thoracic procedure. The patient should be in the semi-sitting posture in bed. The puncture is made with the small trocar of Potain's apparatus, connected with the aspirator, or with a strong and rigid lumbar puncture needle, connected with a glass syringe. The needle is introduced exactly in the midline just below the xiphoid appendage, directed backward and upward, and as it enters is carried more and more in an upward direction, so as to graze the posterior surface of the xiphoid and bony sternum. When the point has traveled four centimeters in children and five or six centimeters in adults, it should lie in the pericardial sac. Through its entrance in the midline the needle avoids the peritoneum—traveling in the subperitoneal cellular tissue—and the muscular fibres of the diaphragm. In a case of acute rheumatic pericarditis in a young man of twenty-two years with endocarditis, cardiac dilatation and constant dyspnea, a position intermediate between that of orthopnea and the kneechest posture being assumed by the patient —followed by constrictive pain at the base of the chest, a thready pulse, and marked cyanosis, epigastric puncture was performed with Potain's aspiration apparatus and 180 grams of serofibrinous fluid was removed. Next day there was distinct improvement, the patient abandoning his peculiar posture, the heart beating more strongly, and the pericardial friction rub resuming its former intensity. Dyspnea later increasing again, three additional punctures were made, but without obtaining fluid. Recovery from the pericarditis, however, soon followed, though a mitral murmur persisted. In spite of the relatively small amount of fluid removed in this case, the puncture, as was manifest to all those present, saved the patient's life. Similarly, in a case of gonococcal pericarditis treated by Robin and Fiessinger, in which a small effusion was sufficient to bring on marked dyspnea, removal of only fifty c. c. of fluid by epigastric puncture completely modified the respiratory condition. The Marfan procedure is advantageous in that, even if the heart should be reached by the needle it is penetrated in a tangential and not a perpendicular direction. In purulent pericarditis, pneumococcic pericarditis in particular, it is only an exploratory measure, and should be followed by pericardotomy and drainage. It is contraindicated where there is tympanites so marked as to obscure the xiphoid and in "funnel breast." It may also fail in the rare cases of chiefly posterior pericardial effusion, in which a misleading "dry tap" may be obtained; in these cases radioscopy is of diagnostic value.

Tunnels and Large Cavities in Bone.—Norman F. Lock (*British Journal of Surgery,* July, 1916) summarizes the treatment of the foregoing conditions as follows: 1. The presence of tunnels and large cavities in bones as the result of gunshot wounds, as well as from other pathological conditions, is a common cause of persistent sinuses, which continue to discharge practically indefinitely. 2. Tunnels occur in cases where a long bone has been perforated and fractured by a bullet, and where, in treating the septic condition associated with these compound fractures, a drainage tube has been passed right through the middle of the bone, the bone uniting around a central cavity. 3. The delay that takes place in the healing of the sinus is due to the fact that a chronic infection is present with which the tissues are unable to deal, since they are unable to obliterate the tunnel, the rigid walls of which will not collapse, so that the sinus which leads down to the tunnel continues to discharge indefinitely. 4. Attempts at sterilization of these cavities and tunnels by scraping and the use of disinfectants are almost uniformly unsuccessful, and, therefore, the use of such materials as bismuth paste or iodoform paste is doomed to failure. 5. The treatment advised is the subperiosteal resection of one wall of the tunnel, access being gained by longitudinal incisions down to the bone, at right angles to the length of the tunnel, so as to convert the tunnel into a shallow trough or groove; the trough so made is drained through the more dependent incision, and the bridge of soft tissues is pressed down into the bone by firm bandaging. 6. Large cavities in bone are treated in a similar way, bone being removed subperiosteally so as to convert them into shallow troughs. They are drained by a suitably placed counterincision, and the bridge of soft tissue is pressed down into the trough so as to obliterate the cavity.

Miscellany from Home and Foreign Journals

Ateleiosis.—F. Parker Weber and G. F. Stebbing (*British Journal of Children's Diseases,* July, 1916) reports a case of ateleiosis, a kind of general and symmetrical dwarfism and infantilism which is due to more or less complete bodily and mental arrest of growth and development. It is not confined to any portion of the body. The whole body is affected. These dwarfs differ according to the period at which relative or absolute arrest of growth and development has occurred. It is probably of endocrinic origin. The sexual glands are usually hypoplastic and defective. The family history of the case reported is negative, both as regards the mother's and the father's family. Thyroid was given without improvement. The administration of thyroid seemed to make the patient worse mentally.

Carbon Monoxide Poisoning.—Yandell Henderson (*Journal A. M. A.,* Aug. 19, 1916) states that extensive investigation of this common form of poisoning has shown that this gas is physiologically inert, with the single exception of its affinity for the hemoglobin. Through its union with the hemoglobin it prevents the carriage of sufficient oxygen to the tissues, and it is this which leads to the symptoms in the acute stages, and the damage done which accounts for the persistent symptoms. Contrary to general belief the compound of carbon monoxide with hemoglobin is not permanent, and is broken down fairly rapidly after removal of the patient from the atmosphere. This restoration of oxyhemoglobin may be hastened by the administration of oxygen. Bleeding and transfusion of blood are more likely to be harmful than beneficial. Since there is a marked acidosis in this form of poisoning, the administration of alkalies would theoretically seem to be indicated.

Herpes recurrens.—H. G. Adamson (*British Journal of Children's Diseases,* July, 1916) points out that herpes febrilis is present in forty per cent. of the cases of lobar pneumonia and malaria and often in such conditions as cerebrospinal fever, scarlet, influenza, typhus, diphtheria, typhoid, relapsing fever, smallpox, and nondiphtheritic angina. The nerve disturbance causing herpes febrilis may be due to some toxin common to the infections with which herpes febrilis is associated, this toxin having special affinity for nerve tissue and the sensory ganglia. At times the specific germ is found in the vesicles; pneumococci and diphtheria bacilli have been isolated from these vesicles. In recurrent herpes of the face the eruption usually appears for the first time at the age of three or four years and affects the left cheek more often than the right. The etiology is obscure. Recurrent herpes of the gluteal region has been considered to be a manifestation of latent or declared gout. As to the treatment, any source of reflex irritation such as adenoids, dental trouble, defective eyesight and intestinal worms, should be remedied. Two to five grains of quinine at the beginning of an attack may cause it to be aborted, as also the local application of collodion before the vesicles have matured, or calamine lotion if they have already formed.

Irreparable Paralysis of the Median Nerve.—G. Axhausen (*Berlin. klin. Woch.,* Feb. 14, 1916) reports the case of a soldier in whom there was complete severance of the median nerve beneath the supinator brevis muscle where the nerve divides into its several branches. Since the nerve could not be sutured at this point, tendon transplantation was performed. The tendons of the paralyzed extensor muscles were united to those of the flexor carpi ulnaris, and those of the extensor and abductor pollicis to the flexor carpi radialis. The union was made through the interosseous membrane. Lateral chiseling into the wrist joint was done to procure a limitation of mobility of this joint. Eight weeks after the operation the patient had power of actively extending the fingers, and he learned to use his hand satisfactorily for a variety of purposes.

Laparotomies in Gunshot Wounds.—G. H. Stevenson, J. J. M. Shaw and C. Mackenzie (*Lancet,* July 29, 1916) have learned from a fairly wide experience that success in the treatment of gunshot wounds of the abdomen depends largely upon the length of time elapsing between the injury and the operation; the shorter this interval, the better the chances. A second point of importance is the early recognition of the presence of an intestinal injury. In this connection it was observed that injury to the intestine occurred at times, even when the missile had not penetrated the peritoneum. The best results were secured when the laparotomy was associated with saline lavage of the abdominal cavity and thorough excision of the tissues forming the walls of the wound. The intraperitoneal use of ether as an antiseptic was abandoned except for localized infections, on account of the great shock it caused.

Influence of Altitude on the Nervous System.—George A. Moleen (*Journal A. M. A.,* August 12, 1916), discussing the widespread belief that great altitude tends to increase nervousness and nervous irritability, cites evidence in support of this belief. Many persons, otherwise normal, manifest a hyperexcitability at great altitudes which may involve the motor, sensory or psychic spheres or any combination of them. Such manifestations, however, are uncommon and are not encountered in persons truly normal, but only in those sufficiently abnormal to fail to became acclimatized. From a review of the studies made upon the physical effects of great altitudes we find physiological reasons for the development of the nervous symptoms. At great altitudes there is an increased demand for the oxygen carrying elements of the blood which is met in normal individuals in three to five weeks by an increase in both the hemoglobin and the number of red cells. The want of this power of adaptation or some deficiency in it occurs in certain persons, and it is these who are affected by the increased nervous hyperexcitability. By removal of such persons to a lesser altitude and the administration of iron in a form which will lead to an increased production of hemoglobin, they may be cured in many cases.

Fibroids. — John Bland-Sutton (*Brit. Med. Jour.*, July 29, 1916) offers the following useful suggestions, based upon an experience of over 2,000 operations for fibroids. The differential diagnosis is often difficult between solid tumors of the ovary and large subserous fibroids, and between uterine fibroids and tubal swellings. It is unwise to express an opinion on a pelvic swelling without a vaginal examination, or on a hypogastric swelling without passing a catheter. Fibroids should not be removed in any case without excluding the presence of diabetes, for coma will often follow the operation in a few days. Urinary retention in a barren woman thirty-five to forty-five years of age is almost certainly due to a uterine fibroid. When a fibroid suddenly becomes painful during pregnancy, with symptoms resembling those of tubal gestation, rotation of an ovarian tumor, or acute appendicitis, the fibroid will be found in a state of red degeneration. Mistakes in differentiating fibroids and pregnancy usually occur before the fetal heart is audible. Subserous fibroids may be simulated by cancer of the pelvic colon. When, in a young woman, there is doubt whether a uterine enlargement is due to fibroids or to pregnancy, we should wait a month and make a reexamination. Fibroids are more dangerous than ovarian tumors in pregnant women, on account of their liability to become septic. When a fibroid is removed from a woman in her procreative period, she is more likely to acquire more fibroids than to conceive successfully. The operation of partial hysterectomy for troublesome fibroids is nearly devoid of danger, and there were no deaths in the author's last consecutive 200 operations.

Diagnosis of Functional Heart Murmurs.— P. E. Weil (*Paris médical*, July 1, 1916) states that the maximal intensity of functional murmurs on auscultation does not correspond with that of the recognized organic murmurs; they are but slightly, or not at all, transmitted; they are generally superficial, soft, and veiled; they are almost always systolic in time, but generally begin before the first sound and end before the second; they are very variable at different times or even during a single examination, are most marked in recumbency, are sometimes attenuated by deep breathing, and are greatly enhanced by excitation of the heart through emotion or physical effort. The ordinary soft, superficial, and untransmitted functional murmurs are readily recognized. In the differentiation of the more intense, harsh, and transmitted functional murmurs, but little influenced by postural changes and deep breathing, Weil has found that compression of the eyeballs, which acts as a sedative on hearts in a state of erethism and causes functional murmurs to disappear, is of great diagnostic value. Organic murmurs, on the other hand, are rendered stronger or more distinct by ocular compression. In the normal heart, ocular compression causes usually a slight slowing of the heart beat—ten beats per minute on the average—though occasionally the rate is slightly accelerated, and rarely remains unchanged. Hearts with functional murmurs all react in a special manner, the rate being immediately or within ten or twenty seconds lowered from eighty, 100, or 120 to eighty, sixty, or even forty a minute; the rhythm, previously regular, becomes irregular when the rate is greatly slowed; the murmurs, meanwhile, at first attenuated by the maneuvre, later become inconstant and disappear. The murmurs may be made to reappear, more clearly than before, by having the patient run. Renewed ocular compression is then even more effective than before, the rate dropping from 120 or 140 to as low as twenty-five. By the use of this test the authors readily cleared up a series of complex cardiac conditions. Many supposed instances of pulmonary or aortic stenosis or of mitral insufficiency were found to be nonexistent, and it was learned that rather frequently functional and organic murmurs coexist, ocular compression causing, for example, loud basal or apical exocardiac murmurs to disappear, only to reveal a mild mitral regurgitant murmur, previously inaudible. By combining with the ocular test Martinet's procedure of investigating circulatory functional efficiency by recording the pulse rate and blood pressure during rest and after exertion, Weil was markedly successful in differentiating functional cardiac disorders, insignificant in their bearing on general physical resistance, from organic disease.

Disturbances of the Visual Apparatus in Traumatism of the Orbit by Firearms.—Lagrange (*Bulletin de l'Académie de médecine*, June 27, 1916), from observation of 179 cases of fracture of the orbit without destruction of the globe, is led to formulate five axioms relating to the eye disorders resulting from such wounds. 1. When the projectile passes above the orbit, striking the frontal bone and the anterior cerebral region, it entails radiating fractures which react, at the optic foramen and the sphenoidal fissure, on the special sense, motor, and sensory nerves of the orbit; the eyeball, however, remains uninjured. 2. When the projectile passes below the eyeball, without entering or fracturing the orbit, it causes lesions due to concussion reacting on the eye in the macular region; this is the main cause of central disorders of vision. 3. When the projectile has fractured the orbit, driving in its wall more or less deeply without touching the eyeball, it produces in the latter grave lesions due to concussion, including macular disturbances and ruptures of the choroid; the macular lesions are distinct whether it be the outer, inner, or inferior wall of the orbit which has been injured, while the choroid lesions are found opposite the fractured wall. 4. When the projectile has passed through the orbit without touching the eyeball, the same disorders are produced, and such disorders as result from laceration of the structures contained in the orbit; the optic nerve is often cut, the pupil being in this case lacerated, as though torn out. 5. When the projectile touches the eyeball tangentially, without rupturing it, disturbances occur immediately opposite the torn point, e. g., chorioretinal tears with detachment of the retina and proliferating retinitis; the macular region is, in these cases, often involved in these disturbances, but is not separately affected, as in 2 and 3. Lagrange presents histories of cases showing the solidity of the principles he enunciated.

Radiodiagnosis of Appendicitis.—George Vilvandre (*Archives of Radiology and Electrotherapy*, July, 1916) reports a case in which the diagnosis of paratyphoid and cholelithiasis had been made. The right iliac fossa was investigated with the x ray and a concretion was found, which made the diagnosis of appendicitis positive. In making the differential diagnosis between ureteral calculi and calculi of the appendix, it is important to remember that ureteral calculi are situated more internally. An error of interpretation will be possible only when the appendix lies in the three o'clock position, over the psoas and hanging over the brim of the pelvis. In order to do this the appendix must be much elongated. Impacted gallstones, or one in the lower end of the common bile duct, will appear at a higher level. There is no added risk entailed in radiographing just before operation. Another advantage of taking an x ray picture is that the appendix is localized and the surgeon need not hunt for it.

Appendicitis Complicating Pneumonia. — J. Allan (*British Journal of Children's Diseases*, July, 1916) cites the history of a case admitted to the hospital with the diagnosis of acute appendicitis. The symptoms were entirely abdominal and the spot of greatest abdominal pain was in the right iliac region. Examination showed general abdominal tenderness on palpation, particularly over the area of the appendix, and the abdominal muscles in that region were distinctly rigid. There was marked tenderness over McBurney's point. The examination of the lungs was negative. The appendix was removed and it was found to be inflamed, and to contain a blood clot. A mixture of chloroform and ether was used as the anesthetic. The following day a troublesome cough developed and the temperature at 6 a. m. was 103.6° F. Two days later the temperature fell from 103.6° to 96° within thirty hours. This was clearly a case of pneumonia complicated by appendicitis, the infection of the appendix being probably caused by the pneumococcus.

Trench Diarrhea.—F. Rathery and L. Bisch (*Presse médicale*, July 6, 1916) discuss the etiology of trench diarrhea, and assert that many instances of it are merely cases of dysentery. Systematic serum diagnosis for dysentery bacilli and examination of the stools for amebas has frequently shown this to be true. At times, however, as exemplified in four cases which the authors report, no amebas can be found, and yet emetine hydrochloride is remarkably effective. These cases, though apparently mild at first, are in reality serious, becoming complicated by large, typical liver abscesses. In the four cases reported surgical treatment of the abscess uniformly resulted in recovery. Chocolate colored pus was evacuated which was entirely sterile and free of amebas, as were also fragments of the abscess wall. Nevertheless the cases are considered to have been instances of true, but larval, dysentery. In many other cases of dysentery efficiency of emetine, in spite of the absence of amebas from the stools, was observed. In the four cases reported the signs of hepatic involvement were not marked, consisting merely of a slight dullness anteriorly or posteriorly, without polynuclear leucocytosis. The diagnosis was chiefly based on x ray examination.

Localized Osteospondylitis.—Willis C. Campbell (*Journal A. M. A.*, Aug. 19, 1916) states that this disorder does not seem to have been generally recognized, and that the literature contains no reports relating to it. The condition is sharply localized to a single pair of vertebræ, and is an osteoarthritis, producing lipping of one of the affected bones and more or less complete union with its neighbor, so that the two vertebræ become immovable upon one another. In the acute type, the symptoms resemble those of spinal tuberculosis, and in the subacute or chronic type, pain is the chief symptom. The pain is usually referred, so that the condition is often mistaken for some form of abdominal visceral lesion. Thus one patient was operated upon several times for one or another form of abdominal lesion, and another had the diagnosis of renal calculus made. The diagnosis of the condition can be made only as the result of careful radiography which reveals the presence of lipping or the formation of a complete ring of new bone surrounding a single intervertebral cartilage. The etiology seems to be the same as that of other forms of uniarticular osteoarthritis. In one of the cases it was due to pneumococcal, and in another probably to gonococcal infection. Relief was permanently secured in the three cases, treated by more or less prolonged immobilization of the spine through extension on a Bradford frame.

Sinoauricular Block Due to Tobacco Poisoning.—S. Neuhof (*Archives of Internal Medicine*, May, 1916) states that while it has long been known that overindulgence in tobacco causes cardiac arrhythmias, the exact nature of these has not as yet been determined with the aid of the modern graphic methods. In his own experience he has known of several cases of extrasystoles (premature beats), one of auricular flutter and one of auricular fibrillation due to tobacco poisoning. In a recent case, however, that of a man of twenty-eight years who had been smoking uninterruptedly since the age of fifteen years and used three cigars and three pipefuls a day, a condition of sinoauricular block—standstill of the entire heart—was revealed, one beat in every three to five beats being completely missing, with entire absence of the heart sounds. The length of most of the pauses was somewhat less than two normal beats. There was no evidence of organic cardiovascular disease in this case, and no symptoms were produced by the arrhythmia. In another case, that of a man of fifty-seven years averaging thirty cigarettes daily, ventricular extrasystoles and sinoauricular block were both present, together with slight myocarditis and nephritis. Under cessation of smoking and moderate doses of bromides, the sinoauricular block disappeared in three days, but the extrasystoles persisted, only to disappear, in turn, under digitalis, theobromine, and the Karrel diet, compensation having been fully restored. A different origin of the two forms of irregularity is thus strongly suggested. The sinoauricular block is ascribed to excitation of the vagus by the tobacco, this inhibiting the cardiac "peacemaker" in the sinus region of the heart. Such an action accords with observations of the action of nicotine on the vagus in experiments on animals.

Proceedings of National and Local Societies

AMERICAN PEDIATRIC SOCIETY.

Twenty-eighth Annual Meeting, Washington, D. C., May 9 to 11, 1916.

The President, Dr. Rowland Godfrey Freeman, of New York, in the Chair.

(*Concluded from page 428.*)

Some Early Symptoms Suggestive of Protein Sensitization in Infancy (*Continued*). — Dr. Oscar M. Schloss, of New York, had made a large number of skin tests in infants with inconclusive results, in chronic nutritional disorders. He stated that sensitization from the absorption of unaltered foreign protein had not been proved to occur regularly in human beings, as in animals. He thought that the idiosyncrasy of some infants to foods that they had never before ingested might be explained by inheritance. In four cases of asthma that had a definite relation to food, he had accomplished desensitization with good results.

Dr. Fritz B. Talbot, of Boston, believed the condition of anaphylaxis giving rise to symptoms of asthma to be a relatively rare one. In looking through the hospital records, he had found very few such cases that might have been of anaphylactic origin, but had found more among the skin cases. Of the respiratory symptoms, he thought that wheezing, when there were no rales in the chest, with no fever and nothing else to explain it, might be of anaphylactic origin. Croup might also be in a few instances, and likewise some digestive disorders, he said.

Early Morning Vomiting in Children.—Dr. Thomas S. Southworth, of New York, directed attention to the vomiting of children, which not infrequently occurred in the early morning either before or soon after the first feeding. This he believed to be of toxic origin, since the vomitus after the long night period contained no food residue unless a morning feeding had been given. It was sharply distinguished, he said, from the vomiting of undigested and fermenting food from failure of gastric digestion, which usually occurred later in the day. The cases, one of which was related as typical, had neither the characteristic histories nor clinical symptoms and course of recurrent vomiting, which was another toxic type. He believed that in the recurrent type the toxemia was probably of gradual and cumulative evolution brought to a head by constipation or some unusual factor. Elimination, he stated, was slow and vomiting prolonged. Fever was not constant. In the type under consideration with early morning vomiting fever was a usual accompaniment, often rising sharply, and there was an acute putrefactive process in the intestine with absorption and attempted reelimination by the gastric mucous membrane. He assumed that this toxic material accumulated in the stomach during the hours of slumber when reflexes were more or less deadened and asserted its presence in vomiting after awakening. Purgation resulted in foul stools often containing mucus. After the stomach was emptied by one or two acts of emesis at short intervals there is not the same tendency to recur which pertained to the recurrent type. He believed that the extreme caution in the resumption of feeding often displayed after attacks of recurrent vomiting frequently led to undernutrition in children whose attacks occurred at rather short intervals, and said that slightly greater care was demanded in the acute toxic type of intestinal origin, especially in the summer months, because of the intestinal condition. With care, however, he thought that reasonable feeding might promptly be inaugurated. The author believed early morning vomiting without food residue from the previous day to be a sign of value as indicating an acute toxemia arising in the intestinal tract.

Dr. DeWitt R. Sherman, of New York, asked whether Doctor Southworth had had an analysis made of the material vomited in the early morning. He thought that such an analysis might afford an indication as to whether there was hyperchlorhydria.

Doctor Talbot asked whether the urine had been tested for acetone in the early morning.

Dr. Isaac A. Abt, of Chicago, was inclined to be skeptical as to the gastrointestinal nature of the vomiting, which, he said, occurred in a great many conditions outside the gastrointestinal tract; for instance, nasopharyngitis.

Doctor Southworth said that he had not made any tests, but thought it probable that some of the children might have had hyperchlorhydria. While a great many children with gastrointestinal disturbances had an odor of acetone in the breath, Doctor Southworth stated that he had made no examination of the urine in these cases. He felt sure that the gastrointestinal condition was the cause of the symptoms in his cases, as these all subsided when the gastrointestinal tract was cleared out. There had been no cough or nasopharyngeal mucus.

A Study of the Etiology of Chorea.—Dr. John Lovett Morse, of Boston, as the result of his investigations, concluded that syphilis played no part in the production of chorea. No microorganisms were found in the spinal fluid, but various bacteria were found in the blood. None except a streptococcus would produce lesions in animals. This organism did produce lesions of chorea in rabbits. The organisms found in the different cases were different. There was a local infection in all the cases in which cocci were found in the blood, so these organisms might have had nothing to do with the chorea. Doctor Morse did not, therefore, consider the bacterial origin of chorea as proved. He thought, however, that chorea must be intimately connected with rheumatism and endocarditis.

Dr. Henry Koplik, of New York, had made a number of cultures for syphilis in cases of chorea with negative results. He thought that there might be a bacterial invasion at first, the bacteria disappearing and leaving behind them the toxin causing the symptoms.

Doctor Abt considered chorea to be the expres-

sion of a state of the nervous system occurring in a variety of conditions. He had collected 225 hospital cases, and had found that the majority of the patients had had chorea for a definite time without any history of a previous infectious disease that could be connected with the chorea.

Dr. B. S. Veeder, of St. Louis, had never been able to get a change in the colloidal bone reaction, indicating that chorea was not a primarily bacterial condition.

Dr. Abraham Jacobi, of New York, announced the forthcoming publication of a paper by Dr. A. L. Goodman on the subject of a new treatment for chorea by which he was able to cure the cases within a few days. The method consisted in injecting into the child some of the serum from its own blood.

Doctor Morse stated that thirty-seven per cent. of the children had had rheumatism in the past or with the chorea, with acute endocarditis and with valvular lesions.

The Effect of Subcutaneous Injections of Magnesium Sulphate in Chorea.—Dr. Henry Heiman, of New York, had tried injecting a twenty-five per cent. sterile solution three times daily for fifteen days in five cases. In none of these was sufficient improvement produced by the treatment to warrant him in giving it a further trial.

The Prognosis and Treatment of Banti's Disease in Children.—Dr. Edwin E. Graham, of Philadelphia, reported a case that he had studied since last August. The child had been under treatment all of this time, and was practically in the same condition as when first seen, except for a slight improvement in the blood count. He was considering the advisability of performing splenectomy, which he thought the proper treatment for a case in this stage. The Wassermann test had been negative, and the patient had no ascites, no jaundice, and no changes in the liver.

Doctor Koplik said that he believed Banti's symptom-complex, if it existed at all, to be rare.

Familial Icterus in the Newborn.—Dr. Isaac A. Abt, of Chicago, related instances of this disease in two families, of five and six children, respectively. There was nothing in the history of either family to show the cause of the disease in these infants. Three children of the first family had died, one on the third day and two on the fourth. In the second family, two children had died of icterus on the third day. The last child had had the disease, but had improved on the fifth day and got well. Doctor Abt said that this disease was quite different from chronic familial jaundice, in which the patients might live to advanced age.

Dr. Wilder Tileston, of New Haven, said that yellow staining of the nuclei of the base of the brain and medulla was never encountered in jaundice in the adult, and that its presence indicated a powerful poisoning. He did not believe familial icterus to be a septic condition. He asked whether fragility of the red cells had been noted in either the mother or the child in connection with this disease.

Doctor Sherman wondered whether these cases of jaundice might not be due to the poison of chloroform, which might produce degenerative changes resulting in death some days afterward.

Doctor Abt stated that the blood had been examined in several of the cases, and no alteration had been found in the red cells. He thought that the mothers had received no chloroform, or very little.

Observations on the Endermal Injection of Diphtheria Toxin with Reference to the Schick Test.—Dr. David M. Cowie, of Ann Arbor, said that these endermal tests had been made in twenty-three infants, with ten positive and thirteen negative results. Negative reactions were frequent in infants under five months. Young infants, he said, are seldom attacked by diphtheria; and a large number of those under six months of age were immune. He thought that a delay in reaction meant that the individual had a certain amount of immunity. The toxin in minute amounts seemed to stimulate the formation of antitoxin, rather than to use up an appreciable amount of the antibodies already present.

Doctor Koplik emphasized the fact that the preparations of diphtheria antitoxin should be standardized, and said that a definite amount of standardized solution injected under the skin would produce a minimal amount of trauma, and thus practically eliminate pseudoreactions due to this. He had also succeeded in doing away with anaphylactic reactions by this means.

Doctor Hess said that these toxin-antitoxin mixtures would not confer immunity in all cases, a small percentage of children being unable to form antitoxin, as was the case with horses.

Scarlet Fever and Measles Occurring Simultaneously in the Same Family, the Other Children Acquiring Measles Only.—Dr. D. J. Milton Miller, of Atlantic City, said that when scarlet fever and measles occurred together, the diagnosis was extremely difficult, the eruption in measles often being so confluent as to resemble scarlet fever, and the eruption of scarlet fever so morbilliform as to resemble measles. They should be careful to make a diagnosis of double infection when this was present, as in one of the children of the family reported.

Dr. Matthias Nicoll, Jr., considered it impossible to make a certain diagnosis when these two diseases were thought to be present at the same time, because there were no absolutely typical forms of desquamation in these cases. He did not feel that the double character of the infection had been proved in the case of Doctor Miller.

Doctor Miller said that he had not seen the peculiar eruption of the skin and finger nails in any cases that were not scarlet fever, and had based his diagnosis largely on that fact.

Some Observations on Measles.—Dr. Charles Herrman, of New York, said that the deaths reported as due to measles did not give a correct idea of their real number; because a large number were put down as due to the complicating bronchopneumonia, which occurred especially between the ages of one and two years. He stated that infants under two months were absolutely immune, this immunity gradually disappearing, and being entirely absent at the age of eight months. The immunity was probably conveyed through the placental circulation.

Doctor Koplik stated that at the very outset, sometimes five days before the eruption, there was a

febrile movement accompanied with the first appearance of the Koplik spots. When this phenomenon occurred, he was accustomed to isolate the children and wait patiently for the development of the rash.

Doctor Holt mentioned the fact that there was on record another case in a very young baby, five weeks old.

Doctor Hamill asked whether Doctor Herrman wished to imply that it was a good thing to expose children under five months to infection.

Doctor Herrman admitted that it was impossible to be absolutely sure that a baby under five months could not contract the disease, and did not wish to put himself on record as favoring the exposure of any child to a contagious disease; but he said that experience had shown that if these babies were exposed and did contract measles, it was of a very mild character.

Meningitis in the Newborn and in Infants under Three Months of Age.—Dr. Henry Koplik, of New York, believed meningitis in the newborn to be a primary infection in many instances, and ascribed the difficulty in making the diagnosis to the fact that the signs applied later in life could not be applied to newborn infants. Some of the characteristic symptoms could be found, however. He stated that the disease was not always caused by the meningococcus, but that all the cases seemed to be fatal, sooner or later. He considered that the infection might be produced through the methods often resorted to to resuscitate newborn infants.

Doctor Talbot wished to know how Doctor Koplik differentiated between the meningococcus and the gonococcus.

Doctor Miller spoke of a case of meningitis in a newborn baby in which the first symptom was conjunctivitis, wrongly diagnosed as of gonococcal origin. The meningococcus was found on ventricular puncture.

Doctor Herrman referred to the case that he had reported at the 1915 meeting, in which the child did not have even one convulsion. He thought that this indicated that cases in early life were not so infrequent as was believed. He said that in some instances the infecting organism was the colon bacillus.

Dr. J. H. M. Knox, of Baltimore, mentioned having reported a case in which a child only a year old, with beginning hydrocephalus, had been found with slightly turbid cerebrospinal fluid containing the meningococcus. There was only a very indefinite history of meningitis in the case.

Doctor Abt asked whether there was any difficulty in differentiating meningitis in the newborn from meningeal hemorrhage, cerebral abscess, or sinus thrombosis; and whether there was any difficulty in hospitals in making lumbar puncture in the cases of newborn infants.

Doctor LaFetra said that meningitis was frequent as a part of general sepsis in infancy, without the symptoms of meningitis. He thought that if lumbar punctures were done and autopsies made more frequently, more of these cases would be found. He referred to an interesting case in which pus containing the meningococcus was known to have developed in the cord within two days.

Doctor Koplik said that he did not know anything about the minutiæ of bacteriology. He stated that when there was a slight fever in the newborn, it was difficult to differentiate between meningitis and ordinary meningeal hemorrhage. He had not seen sinus thrombosis in any of these infants. The members of the staff at his hospital, he said, had no trouble in performing lumbar puncture. He hesitated to perform lumbar puncture in a newborn baby unless he felt that delay would harm the child and was not certain as to the diagnosis.

The Use of Salt Solution by the Bowel (Murphy Method) in Infants and Children.—Dr. Edwin E. Graham, of Philadelphia, considered this method of more value than was usually thought. He had had gratifying results from its use in cases of pylorospasm, erysipelas, and typhus fever. The enemata should be given slowly, trickling into the rectum at the rate of half a pint an hour. It should be kept at a temperature of 98° to 100° F.

Doctor McClanahan said that infants from two to six days of age often suffered with what was called "inanition fever."

Doctor Abt had not met with a great deal of success in keeping the tube in place, on account of there being considerable irritation around it. He thought that giving the child water to drink by rectum would cause it an increased amount of labor that might cost a weak baby its life.

Doctor LaFetra said that he used an inverted thermos bottle for holding the liquid, in order to keep it at the proper temperature.

Doctor Graham said that in his cases he had given the fluid by rectum because it was impossible to introduce it through the mouth and the stomach.

Pseudorubella in Infancy.—Dr. Thompson S. Westcott, of Philadelphia, had observed ten cases resembling mild rubella that had not been preceded by similar attacks or by rubella in other members of the family. The patients recovered promptly. All the children were under two years of age. The rash was lighter in color than that of true measles, and did not simulate the scarlatiniform type of rubella. It faded rapidly, leaving less pigmentation, and showed no desquamation. It was practically the only symptom of the eruptive stage, and the temperature fell as soon as the eruption appeared. Enlargement of the lymph nodes was the only glandular involvement. It was of independent origin, and not secondary to irritation of the skin surface.

Doctor Nicoll thought the fact that the disease was not contagious and that there was no wave of true rubella sufficient reason for not mentioning the name rubella in connection with it.

Doctor Westcott said that he had called it pseudorubella merely as a program title. He did not know what the disease really was.

The Energy Metabolism of a Cretin.—Dr. Fritz B. Talbot, of Boston, had studied a typical cretin of three years and eight months in the Benedict respiratory chamber of the Massachusetts General Hospital, and had found that when the child was quiet, he produced thirty-nine to forty-two calories to the kgm. of body weight. This was relatively lower than in normal babies. The metabolism, estimated on the basis of body surface, was

also relatively lower than that of two normal babies of eight and a half and ten months.

Doctor SEDGWICK said that at Minneapolis they were doing work on creatin-creatinine in all the cretins they could get a chance to study, and had seven hundred unpublished records. In a case of hypothyroidism, they had given the child desiccated thyroid, and had found that the creatin-creatinine excretion jumped up markedly. This was considered as an evidence of increased metabolism.

Doctor TALBOT thought there must be some connection between the creatin or creatinine and the amount of active protoplasmic mass in the baby, which also seemed to have an influence on the amount of metabolism.

The Dangers from Carriers of Diphtheria to Hospital Efficiency.—Dr. SAMUEL S. ADAMS and Dr. FRANK LEECH, of Washington, reported an epidemic of diphtheria at the Children's Hospital, due to the admission of a child with pneumonia who proved to be a diphtheria carrier. The wards had to be closed for the admission of new cases for three weeks, greatly crippling the hospital's efficiency. The speakers suggested that a ward should be provided for the detention of new cases until opportunity had been afforded to observe them. Visitors should be restricted to adults, and these should be admitted as infrequently as possible.

Doctor GRAHAM thought that having a detention room and making cultures of the nose and throat would be of no use unless adequate provision was made to exclude not only children, but also adults, from visiting the wards. He said that at the Jefferson Hospital they admitted visitors to a balcony from which they could see the children through windows opening into their ward.

Letters to the Editors

ADRENALINE PER OS.

BUFFALO, *August 8, 1916.*

To the Editors:

Referring to the communication by Dr. Leland Boogher, of St. Louis, on this subject, I would say that in 1900 I used adrenaline by mouth quite a good deal as a circulatory tonic, with satisfactory clinical results, so that, for that period, I almost abandoned digitalis. On account of reports of the degenerative processes that might be caused by adrenaline and the general fear of high blood pressure, I discontinued this use of the drug. However, the former reports are mostly based on experimental work with local application of solutions of adrenaline to organs, and some of us are getting around to the idea that it is a good deal better to have too high than too low blood pressure.

I may confess that, at least since 1900, I have very frequently used adrenaline against gastric and intestinal hemorrhages, by mouth, usually with clinical satisfaction, though, as almost all authorities have denounced such administration as worthless, I have not cared to say much about it. However, for several years, I did not have the courage to admit that I could not get a small soft catheter several feet into the bowel without kinking, because every one else told how easy it was.

Directly or indirectly, adrenaline has many advocates as a local anodyne, though mainly when used externally. I cannot say that it has ever had any such effect in gastro-enteric conditions, except after the healing of hemorrhagic conditions, and I do not see just how it could act to relieve pain in a spasmodic condition, such as accompanies gall-stones.

A. L. BENEDICT, M. D.

THE DEPARTMENT OF HEALTH AND ADRENALINE IN POLIOMYELITIS.

NEW YORK, *August 25, 1916.*

To the Editors:

I hope you will permit me some space in your JOURNAL for the following brief remarks of a personal nature.

In my article entitled, The Treatment of Acute Poliomyelitis, published in your issue for August 19th, there are, on page 340, two footnotes which I wish I had omitted; I wish now to correct any erroneous impression which they may have conveyed. It has reference to the supposed inimical attitude of the department of health toward the treatment of poliomyelitis by adrenaline. If I entertained such a supposition before, I know now that I was mistaken, and I gladly apologize to the commissioner of the department for my incorrect public expression. The department was entirely impartial with regard to the choice of the method of treatment, and as far as the adrenaline treatment is concerned, I have the evidence in the fact that more than 100 cases of infantile paralysis were treated by the adrenaline method in the hospitals under the control of the department of health.

S. J. MELTZER, M. D.

THE SERUM TREATMENT OF POLIOMYELITIS.

NEW YORK, *August 22, 1916.*

To the Editors:

Under the foregoing caption the issue of the *Weekly Bulletin of the Department of Health* for August 12th contains statements which require critical analysis. The statement which interests us chiefly reads as follows: "Among the various methods advocated for the specific treatment of poliomyelitis several deserve mention as being based on sound scientific principles. One of these consists of using the fluid withdrawn by spinal puncture for reinjections subcutaneously or intramuscularly into the same patient. This method is based on the assumption that the spinal fluid withdrawn from the patient contains the virus of the disease and that the virus injected subcutaneously or intramuscularly will stimulate the production of antibodies which will aid in overcoming the infection. In other words, the method is one of active immunization." Incidentally we may add that the same method of treatment is described in the NEW YORK MEDICAL JOURNAL for August 19th in an article entitled, Autotherapy in Poliomyelitis. I feel confident that not many discerning medical readers of the last named article will be inclined to say that the method is based on "sound scientific principles," and I doubt that this article could exert an extensive undesirable influence upon the therapeutics of poliomyelitis. It is different, however, with the statement in the bulletin; this bears an official stamp and the bulletin is very widely distributed among physicians of this city; many physicians may thereby be induced to employ this method, especially since its execution is comparatively simple. I regard it, therefore, as a duty to analyze this method critically with reference to two points: First, a minor question, whether the method is indeed based on "sound scientific principles," and, second, an important question, whether the method fulfills the cardinal requirement of all therapeutic measures, namely, that they should not contain elements of danger. As to the first question, superficially the method appears to be based on a few indisputable scientific premises. It is based on the assumption that during the active stage of the disease the spinal fluid of the patient contains live virus. This is indeed a fact, as is shown by the work of Flexner and his associates. It is further an established fact that a subcutaneous injection of live virus is often capable of setting up an infection of poliomyelitis. Finally, the method is tentatively based on the admissible assumption that by subcutaneous injections of ineffective doses of the virus, a state of active immunization in monkeys could be established. This is merely a supposition that has not yet been established by experiment; the active immunization which various investigators succeeded in establishing was made, as far as I know, by intracerebral injections. But as stated before, it is an admissible assumption. However, while these premises are thus undisputed, I am certain that the chief conclusion drawn from these premises is not "based on sound scientific principles." No experiments are on record in which monkeys *already sick were cured by subcutaneous injections of live virus.*

Now as to the cardinal point: Whether such experiments have been made or will be made on monkeys *it seems to me quite clear that such therapeutic experiments should never be made on human beings.* The first effect of an injection into a patient of a medium containing live virus, while the disease is still in an active stage, will not be an immediate active immunization, but *an additional infection, which might be sufficient to cause the death of the patient, or, if survived, to leave him with a greater degree of paralysis.* For a better understanding, let us compare the procedure under discussion in acute poliomyelitis with an injection of live typhoid bacilli into a typhoid patient, or with an injection of tubercle bacilli in a tuberculous patient. One of the following conditions is liable to result from such an injection: Either it may, by additional infection, cause the death of the patient after the first injection; or it may, if the added infection is very small, do neither good nor harm; and, finally, it may, after repeated injections with harmless single doses, cause occasionally, indeed, an active immunization with a consequent cure of the patient. On account of the possible fatal outcome, such a procedure is absolutely prohibited in the diseases mentioned. It ought not to be different in poliomyelitis. Assuming that infantile paralysis, which we treat by subcutaneous injection of spinal fluid, has a degree of infection which borders on the danger line—without further increase in the infection, there may still be a chance for recovery. But by the injection of a dose of live virus, be the dose never so small, some degree of a new infection is added and may turn the scales to the fatal side. Furthermore, in surviving patients, it could be asserted, that without the additional infection, there would have been no residual paralysis at all, or the paralysis would have been less extensive. We need not discuss the question whether such subcutaneous injections may sometimes do good; the evident fact that in some cases the subcutaneous injection of spinal fluid containing live virus is liable to do definite harm, prohibits this procedure absolutely in all cases of infantile paralysis.

On the basis of the foregoing analysis I come to the *conclusion that the treatment of infantile paralysis by subcutaneous injection of the spinal fluid withdrawn from the patient is not only not based on "sound scientific principles," but it is absolutely contraindicated and ought to be prohibited by those in authority.*[1]

From the above mentioned article, Autotherapy in Poliomyelitis, we get the information that the stimulus for using autotherapy in poliomyelitis was given by the supposed fact that cerebrospinal meningitis appears to respond readily to this treatment. Doctor Laidlaw is quoted there as saying that he thought he was the first to withdraw the spinal fluid in a meningitis case and inject it under the skin. It ought to interest Doctor Flexner to learn that Doctor Laidlaw "had been surprised at the number of apparent cases that *had a sterile spinal fluid, in which prompt improvement might follow its injection under the skin.*" But *"the bacterial cases he had had the misfortune to see late in the disease ended fatally."* If I remember correctly, in dispensing the antimeningococcus serum, Doctor Flexner insisted that it should be injected only after finding Meningococcus intracellularis in the cells of the spinal fluid.

The other method which the bulletin considers as deserving of mention, "consists in treating the patients by means of spinal injections of blood serum derived from persons who have recovered from poliomyelitis." This method has been recently discussed by Doctor Flexner (*Journal A. M. A.*, August 19, 1916, p. 583). It may be recalled here that the favorable experimental results which gave rise to the use of this method in human beings were obtained only when the therapeutic treatment "was begun the next day or from eighteen to twenty-four hours after the infection"—that is, long before the onset of clinical manifestations. As far as I know the subject, no successful experiments have been reported in which the treatment was begun when the disease was already clinically manifest. In human beings we deal only with such conditions, and so far clinical observations do not yet permit a definite conclusion as to the actual value of this method. However, since the spinal injections of human blood serum apparently do no harm, and since there is experimental evidence that the spinal fluid probably contains some degree of substances capable of neutralizing the virus, this method ought to be used; the patients ought to receive the benefit of the doubt. But under these circumstances Doctor Flexner's warning deserves special attention, namely, that "in choosing the person who is to serve as the source of the blood from which the immune serum is to be derived, precaution should, of course, be taken to secure a healthy donor; it would be advisable to fortify the usual clinical examination by a Wassermann test." I would add: and by a tuberculin test.[2]

S. J. Meltzer, M. D.,
Rockefeller Institute.

[1] I am very much pleased to state that since I wrote these lines I have received authoritative information that this treatment has been prohibited.

BACILLUS BULGARICUS.

New York, *August 12, 1916.*

To the Editors:

I am a retired physician of over thirty years' practice in this city, and with the exception of the first few years, my services were always given gratis. My only regret now is that they were not always so given. I simply state this so that there need not be any inference of commercialism on my part in this matter. On account of this, however, I have always insisted on being governed by my own conscience and sense of right in preference to some one's else selfishness and self interest.

When Bacillus bulgaricus was first made known, I investigated it for myself as to its merits and found them to be such that I have never had any reason to think of the remedy in other than the highest terms. In fact, the results I have had from its use have been such that if anybody had told me of them, I should most certainly have not believed them. Now a young man of my acquaintaince has asked my advice in regard to putting on the market a preparation of this remedy in a strictly ethical way solely for the use of the medical profession and thus depending on them for its success. I have hesitated to give this advice until I learned the exact opinion of the voices of the profession—the journals. I have been sometimes led to think that there was some latent prejudice against this remedy, although for what reason I have been unable to fathom. That it is therapeutically a marvel I have assured myself from many years' experience in its use, but you know as well as I do what prejudice in the medical profession means and I would not want to advise my young friend to embark in anything that would not offer some chance of success or that would not be favorably received. Whatever information you gave me on this subject would be greatly appreciated. Perry Dickie, M. D.

[A number of excellent commercial cultures of Bacillus bulgaricus and similar lactic acid ferments are already on the market.—Editors.]

CAN POLIOMYELITIS BE TRACED TO POULTRY?

Norfolk, Va., *August 22, 1916.*

To the Editors:

Poliomyelitis, which is rampant in the large cities of this country, has stimulated the medical profession to investigate the etiology and treatment of this contagious malady.

It is my theory that there is a disease among chickens which the farmers designate "chicken rheumatism," which closely resembles poliomyelitis. The chicken from all outward manifestations appears to enjoy good health, when without warning their legs give way and they become paralyzed. Should they not die in a day or two the paralysis is permanent. The contagion is especially noticeable among Plymouth Rocks and is largely prevalent during the summer months. Now it is my opinion that unscrupulous farmers kill these chickens and send them to the market and this is how the infection obtains its first grip on the victim.

[2] If I understand correctly, the human serum which is used in the city of New York is prepared by the research department of the board of health in a way which is believed to make the tedious Wassermann and tuberculin tests unnecessary. To the serum, which is obtained from the blood of a human being, 0.3 tricresol is added and the serum is then passed through a Birkenfeld filter. The well known head of the research department is surely competent to judge whether this procedure eliminates the necessity for the tests mentioned and especially whether the tricresol and the filtration are apt to reduce the value of the antivirus substance in the serum.

Pathologically, the fowls have a high fever a day or two previous to the attack, and as a rule they are infected with chicken lice. This medium to my mind is largely responsible for the distribution of the infection.

A post mortem examination will reveal a livid appearance of the flesh and of the lice in the flesh. Their action appears to me the same as in phthiriasis corporis among the human family in producing typhus. Now I suggest the following as a treatment for this scourge.

Should the brain and the spinal cord contain the element of infection which produces this disease, would it not be well to make a serum of the brain and spinal cord from those that have survived and are immune from a second attack. Verification might be made microscopically and bacteriologically by inoculation of monkeys, etc.

The thoughts herein expressed are not made in any offhanded fashion, but are the result of careful study of this subject, and I believe the suggestion worthy of investigation.

BENJAMIN I. BERMAN, M. D.

Book Reviews

[*We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.*]

Refraction of the Human Eye and Methods of Estimating the Refraction. Including a Section on the Fitting of Spectacles and Eyeglasses, etc. By JAMES THORINGTON, A.M., M. D., Emeritus Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia, etc. Three Hundred and Forty-four Illustrations, Twenty-seven of which are Colored. Philadelphia: P. Blakiston's Son & Co., 1916. Pp. xiii-407. (Price, $2.50.)

As each of the writer's books, *Prisms, Retinoscopy,* and *Refraction and How to Refract,* appeared, it was commended by us as excellent, and it is not easy to add anything in regard to this one, into which these three have been combined. Some additions and some deletions have been made, and the combination has necessitated a considerable amount of rewriting, although no material changes have been noted. It forms a clear, concise, and sane presentation of its subject from the standpoint of a writer who believes cyclopegia to be *sine qua non* for refraction work. Much good advice is given on homatropine as a cycloplegic, concerning which the reviewer is heartily in accord with the writer, even though it is not in accord with the way in which many physicians employ the drug. The book is one that should be recommended widely for the instruction of students, as there is nothing precisely like it in ophthalmological literature.

Operative Midwifery. A Guide to the Difficulties and Complications of Midwifery Practice. By J. M. MUNRO KERR, M. D., C. M. (Glas.), Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow; Hon. Fellow, American Gynecological Society; Professor of Obstetrics and Gynecology, Glasgow University (Muirhead Chair), etc. Third Edition. With 308 Illustrations in the Text. New York: William Wood & Co., 1916. Pp. xv-725. (Price, $6.)

The author begins this treatise with the statement that obstetrics should no longer be considered as a department of medicine, but rather as a branch of surgery requiring a knowledge and practice of surgical principles. Therefore stress is laid on the preparation of the operator's hands, the instruments, sponges, and in fact general surgical technic. Doctor Kerr prefers abdominal Cæsarean section to either symphysiotomy or pubiotomy early in labor. The method of applying the forceps with the patient in the left lateral position will seem strange to the American reader, as this position is not commonly used in this country. Axis traction forceps are unhesitatingly preferred to the ordinary style for all purposes. The work is based upon the writer's experience in the Glasgow maternity, and the illustrations of the operations were taken from actual cases.

Localization by X Rays and Stereoscopy. By Sir JAMES MACKENZIE DAVIDSON, M. B., C. M. (Aberdeen), Consulting Medical Officer, Röntgen Ray Department, Royal London Ophthalmic Hospital, and X Ray Department, Charing Cross Hospital, etc. With Thirty-five Stereoscopic Illustrations on Special Plates, and Other Figures in the Text. New York: Paul B. Hoeber, 1916. Pp. xi-70. (Price, $3.)

A brief description of the x ray tube and the new Coolidge tube is followed by a chapter on secondary rays and the methods of protection employed against the x ray. Stereoscopy is then carefully considered, several forms of stereoscopes being described. It is shown how misleading a single picture may be. How to localize foreign bodies anywhere, but particularly in the eye and orbit, is carefully explained. In the appendix there are several chapters of interest—one describing the telephone attachment in surgery and another the electromagnet as an aid to localization. There are numerous illustrations of the various devices described in the text—also many beautiful skiagraphs.

Modern Medicine and Some Modern Remedies. Practical Notes for the General Practitioner. By THOMAS BODLEY SCOTT, Author of *The Road to a Healthy Old Age.* With a Preface by Sir LAUDER BRUNTON, Bart., F. R. S. New York: Paul B. Hoeber, 1916. Pp. xv-159. (Price, $1.50.)

This little volume of 159 pages with a preface by Sir Lauder Brunton is written in a pleasing style and has only four chapters. The first is devoted to disorders of the heart, the second to arteriosclerosis, and the fourth to bronchitis and bronchial asthma. The third, on therapeutic speculations and doubts, treats, in fact, of the ductless glands, especially the thyroid and the suprarenals. It is a work of practical everyday use, and its simple style makes it easy reading.

Interclinical Notes

"The faker ultimately is found out." These bold words are from a recent number of the *Christian Science Monitor,* according to *Leslie's* for August 10th, which also believes that the news columns of certain newspapers are not to be relied upon.

* * *

In the *Outlook* for August 16th, there is an article describing the United States Public Health Service by a member, Dr. Ezra Kimball Sprague. Too little is known by the public of this remarkable body of physicians, picked men physically and mentally. They run great risks along the line of duty; eight have succumbed to tuberculosis. Before the secret of yellow fever was discovered, many were sacrificed to that disease. Surgeon General Rupert Blue, just reappointed, says, "by concrete example the people at large—not a few scattered counties—must be shown that tuberculosis, malaria, and typhoid fever are a needless drain upon their vitality."

Meetings of Local Medical Societies

MONDAY, *September 4th.*—Utica Medical Library Association; Niagara Falls Academy of Medicine; Hornell Medical and Surgical Association.

TUESDAY, *September 5th.*—Clinical Society of the West Side German Dispensary and School for Clinical Medicine; Amsterdam City Medical Society; Lockport Academy of Medicine; Syracuse Academy of Medicine; Ogdensburgh Medical Association (annual); Oswego Academy of Medicine; Medical Society of the County of Yates; Medical Society of the County of Tioga.

WEDNESDAY, *September 6th.*—Bronx Medical Association; Elmira Academy of Medicine; County of Rockland Medical Society; Long Island Society of Anesthetists.

THURSDAY, *September 7th.*—Practitioners' Club, Buffalo; Geneva Medical Society; Glens Falls Medical and Surgical Society.

FRIDAY, *September 8th.*—Flatbush Medical Society, Brooklyn.

Official News

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for two weeks ending August 26, 1916:

Cook, F. C., Surgeon. Ordered to the naval training station, Norfolk, Va.

Dunbar, A. W., Surgeon. Ordered to the Naval Academy, Annapolis, Md.

Humphreys, Lincoln, Assistant Surgeon, Medical Reserve Corps. Ordered to the Naval Hospital, Washington, D. C.

Kindelberger, C. P., Surgeon. Detached from the Naval Academy, Annapolis, Md., and ordered to duty as fleet surgeon, Atlantic Fleet.

Leys, J. F., Surgeon. Detached from duty as fleet surgeon, Atlantic Fleet, and ordered home to await orders.

McAllister, A. R., Assistant Surgeon. Detached from the Naval Station, Guam, and ordered to temporary duty, Navy Yard, Mare Island, Cal.

Mink, O. J., Passed Assistant Surgeon. Detached from the Naval Hospital, Puget Sound, Washington, and ordered home to await orders.

Neuberger, J. F., Assistant Surgeon, Medical Reserve Corps. Ordered to Marine Barracks, Port Royal, S. C.

Riggs, C. E., Surgeon. Detached from the naval training station, Norfolk, Va., and ordered to navy yard, Washington D. C.

Vogelsang, W. A., Assistant Surgeon. Detached from the *Marblehead* and ordered to the naval station, Guam, by the September transport.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 23, 1916:

Crohurst, H. R., Sanitary Engineer. Granted eight days' leave of absence from August 18, 1916.

Draper, W. F., Passed Assistant Surgeon. Directed to proceed to New York for duty in connection with studies of poliomyelitis.

Ebert, H. G., Surgeon. Granted one month's leave of absence from August 20, 1916.

Foster, M. H., Surgeon. Bureau letter dated May 22, 1916, amended to grant seventeen days' leave of absence from July 5, 1916.

Frost, W. H., Passed Assistant Surgeon. Directed to report to the bureau for conference relative to poliomyelitis.

Lavinder, C. H., Surgeon. Directed to report at the bureau for conference relative to poliomyelitis.

Lombard, M. S., Assistant Surgeon. Granted one day's leave of absence, August 14, 1916; relieved from duty on Coast Guard cutter *Tampa*, and directed to proceed to New York for duty in the prevention of interstate spread of poliomyelitis.

Magruder, G. M., Surgeon. Granted nine days' leave of absence from August 24, 1916.

Parcher, George, Passed Assistant Surgeon. Bureau letter dated July 14th, amended to grant one day's leave of absence, July 17th.

Perry, J. C., Senior Surgeon. Granted two days' leave of absence from August 21, 1916.

Pettus, W. J., Surgeon. Department letter dated June 27, 1916, amended so as to grant six days' leave of absence from July 17, 1916.

Reimer, H. B. C., Acting Assistant Surgeon. Granted seven days' leave of absence from August 21, 1916, under paragraph 195, Service Regulations.

Robinson, D. E., Surgeon. Bureau letter dated June 5, 1916, amended to grant twenty-five days' leave of absence from July 1st.

Safford, M. V., Assistant Surgeon. Directed to proceed to Boston to assist in the examination of Italian steamer carrying immigrants.

Scott, E. W., Assistant Surgeon. Directed to proceed to New Orleans Quarantine for duty.

Watkins, J. A., Passed Assistant Surgeon. Directed to proceed to New York for duty in connection with studies of poliomyelitis.

Wynne, R. E., Assistant Surgeon. Directed to proceed to Charleston, S. C., to deliver an address on rural sanitation.

Yarbrough, H. C., Assistant Surgeon. Granted one day's leave of absence, August 13, 1916.

Casualty.

Surgeon John Macauley Eager was born in New York city, April 14, 1862, and was graduated from the College of Physicians and Surgeons, Columbia University, in 1887. He was appointed an assistant surgeon in the Public Health Service (then the Marine Hospital Service), February 12, 1891, promoted to passed assistant surgeon, March 26, 1895, and to surgeon, December 19, 1907. He served at various marine hospitals and quarantine stations of the Service, at Naples, Italy, from 1901 to 1905, and as assistant surgeon-general in charge of the Division of Sanitary Reports and Statistics from 1905 to 1909. He was again assigned to duty in Naples, Italy, August 12, 1915, where his death occurred August 17, 1916.

Board Convened.

Coast Guard retiring board convened at the Marine Hospital, Detroit, Mich., at call of the president of the board. Detail for the board from the Public Health Service: Senior Surgeon H. W. Austin, president; Surgeon H. W. Wickes, member.

Births, Marriages, and Deaths

Married.

Foster-Wentworth.—In Brockton, Mass., on Tuesday, August 15th, Dr. Arthur Neville Foster, of Dorchester, and Miss Amy Mildred Wentworth.

Leary-Hayes.—In New Bedford, Mass., on Wednesday, August 16th, Dr. Chrysostom J. Leary and Miss Mary S. Hayes.

Died.

Barrows.—In Worthington, Mass., on Wednesday, August 16th, Dr. Sterling Barrows, aged thirty-six years.

Buswell.—In Epping, N. H., on Saturday, August 12th, Dr. Albert C. Buswell, aged sixty-three years.

Elston.—In Corry, Pa., on Saturday, August 19th, Dr. Gabriel A. Elston, aged sixty-three years.

Emory.—In Saranac Lake, N. Y., on Tuesday, August 15th, Dr. Thomas H. Emory, of Manor Glen, Md., aged forty-five years.

Feuerstein.—In Brooklyn, N. Y., on Tuesday, August 15th, Dr. Elias Feuerstein, aged fifty-five years.

Flagg.—In Moreland Okla., on Friday, August 18th, Dr. Edward E. Flagg aged forty-two years.

Herndon.—In Walterboro, S. C., on Saturday, August 12th, Dr. J. P. Herndon.

Kerchner.—In Hagerstown, Md., on Sunday, August 20th, Dr. Edward Kerchner, aged seventy-seven years.

Lockhart.—In Freedom, Pa., on Sunday, August 20th, Dr. Clarence J. Lockhart, aged twenty-six years.

Morse.—In Centre Harbor, N. H., on Monday, August 14th, Dr. Howard F. Morse, aged thirty-seven years.

Powell.—In Los Angeles, Cal., on Friday, August 18th, Dr. Thomas Powell, aged seventy-eight years.

Pratt.—In Brooklyn, N. Y., on Sunday, August 27th, Dr. William H. B. Pratt, aged seventy-four years.

Roedel.—In Lebanon, Pa., on Saturday, August 19th, Dr. Henry H. Roedel, aged eighty-four.

Rowe.—In Flowery Branch, Ga., on Saturday, August 12th, Dr. William J. Rowe, of Buford, Ga., aged sixty years.

Ruth.—In Petoskey, Mich., on Saturday, August 19th, Dr. Oliver J. Ruth, of Keokuk, Iowa.

Ryan.—In Boston, Mass., on Tuesday, August 15th, Dr. George W. Ryan, aged forty-five years.

Smith.—In Coopersville, Mich., on Friday, August 18th, Dr. Frederick D. Smith, aged seventy years.

Waldron.—In Brooklyn, N. Y., on Thursday, August 24th, Dr. William Francis Waldron, aged forty-four years.

Winslow.—In Rockland, Mass., on Friday, August 18th, Dr. Julia A. W. Winslow, aged ninety years.

TUBERCULOSIS IN RELATION TO FEEBLEMINDEDNESS.*

BY PETER BRYCE, M. A., M. D.,
Ottawa, Ont.,
Chief Medical Officer of the Interior, and Chief Medical Inspector of Immigration for Canada.

I am quite aware that my personal opportunities for collecting information are not such as to entitle me to express any dogmatic conclusions on the subject I have chosen to talk about for a few moments, and yet it is perhaps true that owing to my position as Chief Medical Inspector of Immigration for Canada I have had some phases of so many mental and physical conditions brought to my attention that I catch better the reflection from objects, suited to the eye at long range than if they were brought too near and the angle of incidence were too acute for proper vision.

In his chapter on The Causal Factors of Amentia, Doctor Tredgold, medical expert to the Royal Commission on the Feebleminded, says: "I believe that ancestral tuberculosis is but rarely the direct and sole cause of amentia; but my observations show that, like alcoholism, it has an important indirect and possibly also a contributory influence." He further states: "With regard to persons suffering from amentia I found a pronounced tendency to tuberculous lesions in the families of thirty-four per cent. of cases investigated." He further states: "There can be no doubt that the death rate from tuberculosis is very much higher (nearly four times as much) in the case of aments than it is in the non-defective population." Now at a first glance these statements would seem to prove beyond dispute that tuberculosis plays a very important contributory if not a directly inciting cause in feeblemindedness. Yet Tredgold himself states: "It is to be noted, however, that a history of antecedent tuberculosis rarely occurs alone; in four fifths of my own cases it was accompanied by a definite neuropathic inheritance, while in the remaining fifth, other conditions, usually alcoholism, were also present." It is apparent that statistics on the subject are quite inconclusive, since several possible factors seem to be so commonly present. Recent more exact study inclines to the conclusion that in most Anglo-Saxon communities, whether in Europe or America, the feebleminded of all degrees probably are not less than five per cent. in most; yet if the death rate from tuberculosis be put at 0.15 per cent., and the sick from the disease at ten times as many or 1.5 per cent. in all, we find that there seems statistically no relationship between the two. It must have been frequently forced upon the attention of those who have had much to do with the tuberculized, that one of the most obvious conditions present is what for lack of a better term we call a *nerve instability*. I remember that a good many years ago Doctor Mays, of Philadelphia, wrote many articles to prove that tuberculosis was in every sense a disease of the nervous system, and doubtless we have many clinical conditions during the disease in which nervous symptoms play a most important part. Dealing then with the broad aspects of the probable relationship between feeblemindedness and tuberculosis, we have to go back to that subject which has been for years, and is likely to be for years to come, the occasion of much discussion and investigation, viz., the immutability of *germ plasm*. Without entering into the discussion, I wish again to quote what Doctor Tredgold says after a quite full discussion of the subject:

> I hold that primary amentia is a manifestation of a pathological germinal variation which has been produced by the environment, and that the germinal change is of the nature of a vitiation, that is to say, *it consists of an impairment of the intrinsic potentiality for development, which may be widespread and affect the germ as a whole or which may be less extensive and confined to the neuronic determinant.* At the beginning in most instances the latter is probably the case and the central change is but slight. It shows itself merely in a diminished function stability and durability of the higher, and therefore an increased excitability of the lower cerebral neurones and is revealed clinically as neurasthenia, hysteria, migraine, and the milder forms of epilepsy. We may say in fact that these states are the first indications of the presence of the psychopathic diathesis. Should an adverse environment continue, or should a person so affected mate with one similarly tainted, then in the next generation the neuronic durability will be further diminished and the instability accentuated so that insanity, the graver forms of epilepsy, and early dementia make their appearance. If the process is further continued, the third generation will often be characterized by a tendency to defects of anatomical structure, and there will be a strong probability of one or more of the offspring suffering from amentia. Should this germinal impairment be accompanied by any untoward circumstances during the growth of the embryo, this probability will become a tolerable certainty. Degeneracy is here well established and the well known stigmata indicative of an extensive germinal change, are usually abundant. Finally, a condition of gross idiocy appears with complete sterility, and the family becomes extinct.

*Read at a meeting of the Medical Staff, Otisville Sanitarium.

The breadth of Tredgold's observation and the obviously sane and practical conclusions drawn, make them a convenient basis upon which anything I may say will be based. We all know of mountain valleys in Europe or old time settlements in America where through intermarriage has been transmitted at times a general cretinism or a general feeblemindedness so marked as to give their people special historic characteristics. The story of the Martin Kallikak family so well worked out by Goddard illustrates the fact, and others of us doubtless know family hereditary strains quite as marked although not so well worked out statistically. It is *à priori* quite remarkable that in every work dealing with what we may especially term social diseases, as distinct from the acute infections, viz., tuberculosis, alcoholism, syphilis, and feeblemindedness, we find them so often intermingled that it seems quite impossible to determine, which disease is the determinant or dominant one. For instance, I recall the history of a family, many of whose members have been known to me, and about whom speaking thirty years ago with my father we together in a few minutes counted eighty persons who had shown insanity of a catatonic type with mild delusions and periodical acute manifestations. The lists extended back through five generations known either to my father or myself. They were a family many of whom were noted for their beauty, having delicate complexions with golden hair, but in whom the neurotic manifestations were marked especially by mental instability and in a number of cases were associated with consumption. Speaking generally, the mentality of the various branches of the family was more than usually good, and in two distinct branches, descended from brothers intermarried in the second generations with strong stocks of different races, in two instances produced most favorable results in the fourth generation, in the offspring of two second cousins of the fourth generation who intermarried. In all except the last offspring, the four generations were country or village bred. We may hence fairly assume that the new blood and good rural surroundings have been building directly toward a neuronic stability, while had the high tension of urban life been allowed to exert its ordinary influence, the departure from the normal would continue. It is interesting to compare this family with the Kallikak family whose history is given with so much accuracy in Goddard's book. In this group the cases starting from a low type under adverse physical environment continue on the same or even a descending plane; but in all cases we revert to the same old question: What is the real underlying cause or causes of the phenomena in any given group of cases? Goddard states that of 1,200 cases of feeblemindedness in the Royal Albert Asylum, phthisis is mentioned in 291 families or twenty-four per cent. of the whole; but no evidence is given that the phthisis present in the children in these families was the cause of feeblemindedness. No close analysis evidently was made through an attempt to go farther in these cases. In 327 cases whose family histories have been studied by Goddard, we get a very interesting analysis made—

1. Certain heredity: 164, or 54 per cent.—many relatives feebleminded.
2. Probable heredity: 34, or 11.3 per cent.—some relatives.
3. Neuropathic ancestry: 37, or 12 per cent.—family histories showed various brain affections from apoplexy to blindness.
4. Accidental cases, 57, or 19 per cent.
5. Unaccounted, 8, or 2.6 per cent.

Speaking of tuberculosis as a causative factor in 324 cases, Goddard points out that cases of tuberculosis are scattered through families in all the four groups and their incidence is such as would be accounted for by contagion. Some of these families show many cases of tuberculosis "due to the low social order of these people," and a recent *Social Survey Report on Tuberculosis* in Cincinnati says regarding low wages and tenements: "Such a low subsistence level works like black magic in the spread of tuberculosis." After this statement follow notable statistics by Doctor Goddard, which give only 2.8 per cent. of all the 324 cases studied as being marked tuberculosis on the chart, while he states the percentage of tuberculized in the general population to be from ten to fifteen per cent. He then draws a somewhat remarkable deduction when he says, "This agrees with the view that feebleminded stock may be primitive and possessed of much animal strength and possibly some immunity from disease." The inference is based upon altogether too limited and imperfect data to be of real value, since we find in actual statistics for over 2,000 school children, that in the children of slum areas, largely British immigrants, the feebleminded are over five per cent. of the whole, while the prevalence of tuberculosis has long been known to be directly the measure of bad housing. As I have written elsewhere and as all other sanitary and social workers have observed, "tuberculosis is a disease of house life, not the disease of the pioneer shack town; it is the pest of the densely populated city with its slums, overcrowded work rooms, and factories." Remembering that the statistics do not note more than "the most clearly defined cases of tuberculosis of the lungs," as Doctor Goddard states, and as we further note that the great proportion of the feebleminded cases examined will have been among children in whom consumption is rare compared with other forms of tuberculosis, I think it may be taken for granted that we can draw but few definite conclusions from these data. The study of Goddard's cases shows much the same with regard to alcohol and leads him to the general conclusion that "everything seems to indicate that alcoholism itself is only a symptom that for the most part occurs in families where there is some form of neurotic taint, especially feeblemindedness." If the result of the careful examination of the antecedents of the feebleminded cannot associate them either with tuberculosis or with alcohol as the exciting cause, and leads us to infer that the feebleminded are for the most part descended from the feebleminded, we seem to be forced back upon the conundrum posed by Doctor Tredgold when, speaking of Weismann's, Davenport's and others' theory of *immutability* of *germplasm* which must be assumed to belong to members of the simian family, he says,

"one cannot help wondering how their descendants evolved into human beings at all," and then goes on to say: "I very much doubt whether the phylogeny of civilized man was ever represented by a phase of evolution comparable with that of mental defect . . . In short, I regard the germinal variation present in these persons as a pathological one; as being of the nature of a vitiation, which instead of being of spontaneous origin *is really due to negation or diminution of spontaneity*. How, then, is this impairment brought about? I consider it is primarily due to the action of the environment."

We are thus brought fairly to the crux of our problem. What are we to understand by environment? We have what we call external environment, which is postnatal. The native from the Arctic circle to the equator in every part of the globe is subject to it. The Ojibway Indians of Champlain's time on the shores of Lake Superior are pictured as almost naked in their sun dances and as living on game, fish, and herbs; while the Iroquois had their villages and cultivated lands and great tribal federations. Similarly the Tasmanian bushmen of the southern hemisphere remained savages, while the Maoris of New Zealand nearby were a proud and intellectual race with federated organization and well developed ideas of land ownership. Evidently there is much in transmitted qualities in spite of mere climatic environment. On the other hand, if we compare Colonel Oglethorpe's settlements in Georgia of the people from the slums of London placed where the environment was negro slavery, with the thousands of the criminal class shipped to Australia, we must confess to the potential influence of environment both physical and human in each case. Indeed it is this latter to which we must lend our attention. Take city life with its persistent high tension, with its constant attacks upon the nervous system, both through business and pleasure, whether in high finance or in the competition of trade, whether in the pursuit of science or medicine, or even in the charities and other social work. It appears to me that we have to widen our outlook in order to observe the broad effects of modern urban life on the one hand, and on the other to endeavor to realize what internal environment means. Similarly there is *prenatal* environment. We understand the rapidity of cell multiplication and know that there is cell differentiation in the ovum. We further know that from the simplest particle of vital protoplasm through all the stages of cell evolution up to pyramidal brain cells and those of the ductless glands, such depend upon normal nutrition for their growth; while we learn from feeding experiments, as well as investigations into the antecedents of monsters in animals at birth of the distinctly injurious effects upon young chicks during incubation of irregular heating, deficient moisture, and impure air, as well as of the destructive effects upon the fetus of systemic poisons, whether mineral as in lead poisoning, or of infectious diseases as in smallpox, which often result in its death. But much more serious because more general are the hammering effects, to use a mechanical term, of urban life upon the nervous system. Every observant physician, taking stock of his female patients, endeavors to remove the prospective mother from an untoward environment when he notices the undue strain upon her nervous system. For multitudes of the poorer class, rest is impossible; but Nature with her resources has often, through their habits of labor, supplied the defence of an originally less impressible nervous system with a rugged nutrition, the outcome of physical labor. But to many women the noise, the rush, the excitement in their daily lives results either in a complete nerve exhaustion or in a neurasthenia, though occasionally, in a response of Nature to the demand for an extra output of energy when under physical pain or some great emotion, such as war, an abnormal resistance is developed through the sympathetic nervous system. But it is most true, as expressed by John Martin, that "appallingly common are the cases of girls with these nervous organizations and delicate brains, whose latent maturity has been rendered a torture by the exhaustion following on their conscientious obedience to the demands of school and college, of social work, or society life." The most noticeable gross effects are seen in the general reduction in the birth rate in all progressive countries where urbanization is going on rapidly. Thus Doctor Newsholme, chief medical officer, has estimated that had the birth rate of England and Wales been the same in 1914 as in 1876 there would have been 467,837 more infants born there in 1914 than actually saw the light. In a recent report to the Prussian Diet it was stated that there were 560,000 fewer births in Germany than would have occurred if the birth rate of 1900 had been maintained. It was further declared that the decline in birth rate in Germany in twelve years had been as rapid as that in France in seventy, and that births had dropped seventy-five per cent. more than deaths. The most important speakers at the society dealing with the problem, pointed out that the cause is essentially economic, the average marriage age for men being now twenty-nine and for women twenty-six years. Earlier marriage was urged as tending to lessen syphilis and illegitimacy. There are 180,000 illegitimate children born every year in Germany. The recognition of the serious effects upon the child, in its prenatal stage, as well as upon the mother, of disease and disturbed mental conditions, is illustrated in the very successful work being done in maternity hospitals through the care of the mother during this period. Thus in thirty-four mothers treated in Edinburgh during three months, seventeen had albuminuria, yet thirty-three were safely delivered; but there was forty-six per cent. of stillbirths, although eighty per cent. of the mothers were married. The need for antenatal clinics is thus made obvious.

We have thus illustrated the general effects of environment on prenatal health and may now revert to the direct influence of tuberculosis during this period. All will have noted how the progress of tuberculosis often for the time is stayed during pregnancy. Fetal life often greatly stimulates appetite and nutrition in the mother, only to be followed by a complete breakdown during lactation. During gestation, therefore, it may be that the toxic effects of the tuberculous process

are lessened or that they may act as an immunizing factor in the child; but the large number of tuberculous cases, where the child apparently becomes inoculated directly from the mother after birth suggests that the amount of antecedent immunization must have been small. Regarding its direct effects in promoting feeblemindedness, Tredgold like Goddard says, "I believe that ancestral tuberculosis is but rarely the direct sole cause of amentia; but my observations show that like alcoholism, it has an important indirect and possibly also a contributory influence. This indirect effect is seen in its potency to produce the milder and initial forms of nervous instability in the offspring such as migraine, hysteria, and neurasthenia, a clinical fact which has been frequently noticed." It is very remarkable how in the works of the two great authorities on amentia cited, each constantly turns to the condition of neuronic instability, which finds its daily illustration and expression in the effects of modern urbanization. Let any family physician declare his experience, and he will tell that his chief energies are spent upon patching up systems, where there is anemia, malnutrition, functional disturbances of organs, inability to perform normal duties, and where some nerve whip or tonic is frequently required, much of this condition soon disappearing with rest under changed environment as at some rest cure. In many of this class certain common symptoms are observable, such as an actual dislike or even physical distress at the appearance of the older coarse forms of food such as fats, oatmeal, and so on, and a longing for sweet or spiced foods which excite appetite or stimulate the gustatory nerves. Indeed it is abundantly plain that the food of the well to do in America is usually very different from that of the sturdy immigrant peasant, whether Russian, Austrian, or Italian; while it is very probable that among the other vices of our civilization, that of an irrational dietary and of foods of imperfect nutritive elements due to the robbing our common foods, as the grains, of their salts and vitamines is not the least important. What we are assured of is that though the protective and preventive measures against the direct attacks of tuberculosis and other infectious diseases are being constantly multiplied by science and official supervision, yet the breaking down of the *nerve* defences proceeds constantly through the thousand and one modern influences hammering at our brain through the special senses, such as noises, "movies," and the dissipating effects of abnormal occupations and of irregular hours, which exhaust the physical powers and the ability to resist degenerative or malign causes operating against the normal physical and mental processes. We have observed the phenomenon of how in almost every country, certainly in North America, the urban population of fifty years ago was but twenty-five per cent. of the total, while in the United States and Canada at least fifty per cent. of the total population is today urbanized in cities of 5,000 or over, while probably twenty-five per cent. more are suburbanites and in small villages and towns, leaving but twenty-five per cent. actually engaged in agriculture. The effects of the change upon two succeeding generations are now becoming apparent, and we are seriously asking ourselves, whether phylogeny will disappear in its old normal developmental influences, to be replaced by some modern man-created eugenics, adequate to cope with the changed environment, including habits of life, housing, occupation, and education. We know that our total death rate as in New York has been cut in two in fifty years; but we likewise know that the saving is due almost solely to the application of what we may term artificial methods. To give some instances:

1. We have enormously limited the birth rate, leaving, we are told, just so much more time to care for the newborn.

2. The nursing mother has, however, almost disappeared, while much more time is occupied in the attempts to make the child of the neurotic mother with its hypersensitive nerve reflexes of the digestive organs, digest artificially prepared foods.

3. The child with no green pastures to run in beside the still waters, is at best conveyed from the flat to the nearest park by the typical nurse girl, although, indeed, most urban children are born and bred in the tenement and suffer from all its limitations.

4. The mental environment is artificial under all these conditions, and in northern climates the limitations caused by six months or more of our modern housing have produced and will produce a type which, as Dr. Creighton Browne says, "are distinctly more jumpy than we used to be."

5. My observations and the teachings of psychology based on physiology make it apparent that with the absence of a Nature environment at a time when the special senses are absolutely normal in their ability to receive impressions, the growth of mind, based upon artificial environment, will make it more difficult for each succeeding urban generation to wish to get back or to absorb normally even were the wish present, those elementary Nature impressions, which are still the underlying basis of the thoughts of the modern generation. Whether or not modern social processes will develop their physiological or pathological immunizing changes needed to meet the new life conditions being so rapidly developed under modern peace and war times, as regards urbanization, inventions, and artificial products of every sort, must remain to the future for proof. Meantime the degeneration of tissue or the wearing out process has become statistically recognized even in slow going England, while every hospital, sanatorium, asylum, refuge, and "home"—and their class is ever increasing—is filled with the casualties due to this modern war against normal natural processes.

The following table showing the growth of hospitals and patients in the Province of Ontario is both instructive and hortatory.

	Total Hospitals in Ontario.	Total Patients.	Total Population of Province.	Ratio of Patients in Population.
1880.....	12	5,237	1,926,922	1 in 369
1890.....	24	10,523	2,114,321	1 in 200
1900.....	52	29,761	2,189,947	1 in 72
1908.....	69	46,971	2,280,359	1 in 48
1910.....	78	53,692	2,523,274	1 in 47
1915.....	91	85,759	2,598,320	1 in 30

If by artificial methods we may greatly limit tuberculosis, we still shall have a problem of feeble-

mindedness to attack, which will, for an unknown period under modern life conditions, give our legislators, educationists, clerics, and physicians ample occupation, if they are to solve the problem satisfactorily.

DEPARTMENT OF INTERIOR.

SOME THOUGHTS ON PROSTATECTOMY.*

BY HENRY H. MORTON, M. D., F. A. C. S.,
New York,
Clinical Professor, Genitourinary Diseases, Long Island College Hospital; Genitourinary Surgeon, Long Island College and Kings County Hospitals and Polhemus Memorial Clinic, etc.

The operation of prostatectomy is a subject in which all genitourinary surgeons have taken a very keen interest in the last few years, and I can remember the time, only a few years ago, when the only relief for the suffering caused by a hypertrophied prostate and the retention of urine occasioned by it was to give the old man a catheter in his hand and let him live with it, or die from it, as was more often the case. Today we can remove the prostate surgically with but slight risk and add ten or fifteen years of comfort to his life.

We have found it convenient to adopt the classification made by Guyon, of the Necker Hospital in Paris. Guyon's classification divides cases of hypertrophied prostate into three groups:

When the prostate first begins to enlarge, the patient is said to be in the first stage or premonitory period. In this stage the symptoms are very slight—so slight indeed as to be hardly noticed by the patient. There is a little difficulty in starting the flow of urine, there is some deficiency in the force of the stream, and the calls to urinate are rather more frequent than they should be, especially at night. Now, throughout the day the frequency of urination is but slightly increased—perhaps not at all, but as soon as the patient begins to sleep at night he finds it necessary to get up every two or three hours, and sometimes oftener, to empty the bladder. The reason for this is that during the day the muscular activity keeps up the circulation through the muscles, but at night the muscles are quiet and the circulation slows down, venous stasis takes place, and a passive congestion of the prostate and trigone occurs. This has the effect of increasing the irritability of the bladder, so that the accumulation of a small quantity of urine gives rise to a desire to evacuate the organ.

There is also another condition which partly accounts for the frequent urination at night, and that is the condition of reflex polyuria. These old men with enlarged prostates pass an abnormally large quantity of urine. Instead of passing from forty-five to fifty ounces a day, they pass from eighty to ninety ounces, and that is particularly the case at night, because it is then that the greatest amount of secretion takes place.

During the first stage or premonitory period we pass a catheter into the bladder after the patient has urinated and find no accumulation of residual urine, indicating that the bladder is still capable of emptying itself. This, however, soon passes over into the condition of the second stage of insufficiency of the bladder, as it has been termed by Guyon, and this stage is characterized by partial retention of urine, and the frequency of urination increases by day as well as by night. The patient notices that he has to evacuate his bladder more frequently, and there is an unsatisfied feeling as if some urine remained behind in the bladder, and on introducing the catheter residual urine is found in more or less quantity. This condition of the second stage or insufficiency of the bladder may last for several years, but in the end it is bound to terminate in a condition of complete retention.

In the third stage, which is described as the period of incontinence, the bladder is incapable of emptying itself spontaneously and becomes enormously distended, reaching as high as the umbilicus and holding perhaps as large a quantity as two or three quarts. With this overtaxed, overdistended bladder, the sphincter relaxes every few minutes, allowing the escape of a few drops of urine, and when we question one of these old men about his urination, asking if he passes water frequently, and he says, "Yes, every few minutes—" that always means an overdistended and dribbling bladder. This condition has been described as paradoxic ischuria; that is to say, while there is retention of urine in the bladder there is a dribbling from overflow.

Up to this time the patient has been free from constitutional disturbances, but with an overdistended bladder, dilatation of the ureters, damming back of the urine on the kidneys, dilatation of the pelvis of the kidneys, and the added factor of infection, first of the kidney pelvis and then of the parenchyma, other conditions, namely, pyelitis, nephritis, and pyelonephritis, are established, and the patient begins to suffer from constitutional disturbances. That he has these disturbances is due to the absorption of toxic material from the bladder and kidneys, which gives rise to the condition described as urosepsis. The patient now seeks relief because he is sick. The old man comes into the doctor's office and tells you that he hasn't felt quite up to the mark lately. He complains of his stomach and of digestive disturbances. There is emaciation. He complains of being heavy, of not being alert mentally, and sits down in a chair to read the newspaper and drops off to sleep. You ask him as to his bladder and he tells you that he has to pass water frequently, too frequently—in fact, every few minutes; and, generally, you will notice a smell of urine about these old men from the wetting of the clothes, due to the escape of a few drops of urine at frequent intervals. On examining him it will be found that he has a slight rise of temperature, of perhaps a half or one degree. The tongue is dry and brown and exceedingly characteristic of the condition of urosepsis. On palpating the abdomen, the skin is found to be emaciated, dry, and scaly, and on placing the hand over the suprapubic region you find a big fluctuating tumor of an overdistended bladder. That is a typical picture of the third stage or period of incontinence of hypertrophied prostate in old men.

*An address delivered before the Academy of Medicine of Northern New Jersey, April 19, 1916.

The diagnosis of these conditions is made by examination. Of course, the history in itself is sufficiently suggestive, and a man has an idea what to look for and expect when a patient of that type comes into his office. Now, the next thing is to make an examination in detail and find out what condition he is suffering from. We make a rectal examination. We palpate the prostate, and ordinarily

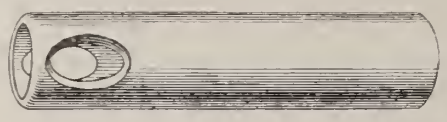

Fig. 1.—Freyer's drainage tube for suprapubic prostatectomy.

we find a prostate which is enlarged, moderately soft, and freely movable in the pelvis. The next point to be determined is the quantity of residual urine and that is really the crux of the situation, because upon that factor depends the question of operation. The amount of residual urine is determined by asking the patient to void, and afterward passing a catheter and drawing off what is left; we may find two, four, six, eight, or ten ounces, or there may be two or three quarts.

The cystoscope is not indispensable in diagnosis, but sometimes it is very useful; there are times when

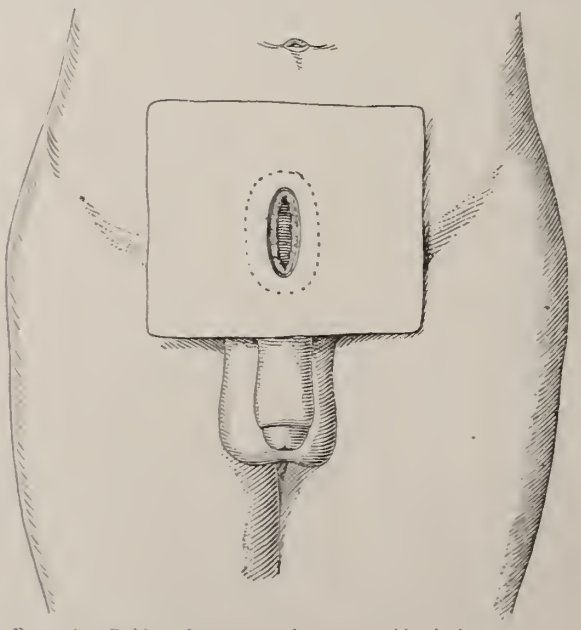

Fig. 2A.—Rubber dam apron for suprapubic drainage, open.

we cannot make a diagnosis without it, and yet there are cases where it is not called for. That is where individual judgment comes in. The cystoscope, however, enables us to determine the presence of stones in the bladder, and the trabeculæ, which usually exist as a result of straining, and also enables us to find a cystic diverticulum, a condition which is frequently present; and now and then we are able to make a diagnosis with the cystoscope where we should not otherwise be able to. I recall a case which I saw several years ago of a man about fifty-five years old (not very old) who had made the rounds of a number of hospitals on account of retention of urine. He had been examined in various places and no enlargement of the prostate could be found. I examined the prostate per rectum and could find no enlargement. It seemed to be perfectly normal in size, and yet the man had retention of urine and could not pass water. He came with various diagnoses such as beginning tabes, paralysis of the bladder sphincter, lesions of the spine, syphilis, etc.; and the nervous system was thought to be involved, but on thorough examination, going over his reflexes, we could not find anything wrong with the nervous system. So, to make sure, we introduced a cystoscope into the bladder, with the result that the diagnosis was established at once, for there was found to be an enlargement of great size of the middle lobe. That was what had prevented him from passing water. I did a perineal prostatectomy, and he was all right afterward. Now that was a case where the cystoscope came in very nicely and established the diagnosis, but, as I say, the cystoscope is not indispensable. However, it is of advantage to know all that we can about a case before operating, but sometimes there are reasons why it is better not to use the cystoscope.

The really essential test, however, in making a diagnosis of hypertrophied prostate is to know the secreting capacity of the kidneys, and the fact should be borne in mind that the determination of this point is essential, and if I were to know only one thing about a case I would rather know that than anything else, for that is the test which really determines whether it is safe to operate. In these old men with enlarged prostate, particularly in the third stage, the urine is of low specific gravity, 1008 or 1010, poly-

Fig. 2B.—Rubber dam apron for suprapubic drainage closed and enveloping folded gauze over wound.

uria exists, casts may or may not be found, and pus is generally present, but there is polyuria, the specific gravity of the urine is low, and the urea is very low. As the condition improves under treatment the specific gravity increases and the quantity of urine decreases. The specific gravity and quantity give us a little line on the functional activity of the kidneys, but the phenolsulphonephthalein test of Geraghty and Rowntree is our chief reliance as to the functional capacity of the kidneys.

This I consider indispensable before deciding to operate, and it should be done as a routine procedure in all cases before operation, and we should not make the mistake of operating in a case if the phthalein is low. In cases where I have operated with a low phthalein I have always regretted it.

Having made our diagnosis, not only of hypertrophied prostate, but also of the general condition of the patient, and especially of the functional activity of the kidneys, the question arises as to the choice of the best time for doing the operation, for

removal of the prostate, and today our attitude is different from the one which we took fifteen years ago. The operation today carries with it a low mortality on account of improvements in the technic, in the postoperative and preoperative treatment, and in the operation itself.

The ideal case for prostatectomy is a patient in the second stage, where the insufficiency of the bladder is beginning and not very marked, where there is perhaps a quantity of residual urine, say, four to six ounces, no cystitis, and where the kidneys are sound. Such a patient is usually in pretty fair condition and he hesitates as to whether he wants to take the risk of having an operation done or whether he would prefer to go along living a catheter life for a while, and when that becomes unbearable have an operation. I think that we ought to take the stand today that, on account of the reduced mortality rate, it is safer for a patient to have an immediate operation rather than to temporize with a catheter. A man

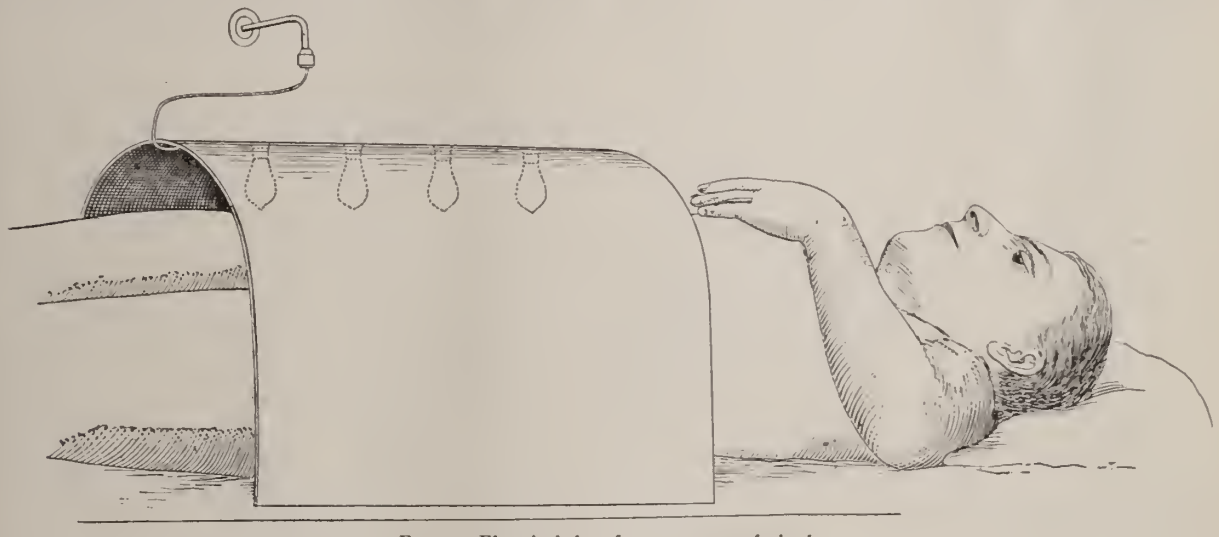

Fig. 3.—Electric baker for treatment of shock.

can be operated on with this condition with a mortality rate of about five per cent. or even less. If we put a catheter in his hand we know that he is going from bad to worse. The catheter will become more and more painful to use, he will have to use it more frequently, he will get up a cystitis, he will have an ascending infection—pyelitis—and in the course of a few months' or a few years' use of the catheter he will get to the point where the catheter can no longer be used and he begs and prays for relief through operation, but his condition has become such that operation will not hold out much in the way of success on account of the disease of his kidneys and generally rundown condition.

Is it not better to take a man in a condition to stand operation and operate with a mortality rate of five per cent. than have him run along for a few months or few years and pass on into a condition where operation is hopeless and nothing can be done? When these people present themselves and ask my advice, I explain that while they take some slight risk at this time it is very much less than if they allowed things to go along and ultimately come to operation with a bad outlook.

The practical points which have resulted in the lowering of the mortality are the details of the preliminary and subsequent care of patients. The treatment before operation I consider absolutely essential. I would not operate on a prostatic patient unless I had him under my care sufficiently long to get him into shape to stand the ordeal.

One very great mistake is to catheterize a patient with a full bladder and draw off all the urine that it contains. Take a bladder which is distended up to the umbilicus with two or three quarts of urine; if we draw all that urine off at once with a catheter, we probably have handed the man his ticket across the Styx and he will die within a week. Now, what will he die of, sudden emptying of the bladder? Yes, indirectly, but what he will die from really will be the sudden relief of the back pressure on the kidneys. In cases where there is a long distended bladder, the patients are in a critical condition. They are in that state of balance where it takes little to tip them over the wrong way. The sudden relief of the distended bladder throws the kidneys into a state of acute congestion, they stop functioning, and the patient dies in three or four days from uremic poisoning. Where we have a patient with a full bladder we never empty it at once, but always gradually. It takes about a week to get such a bladder empty. We put in a catheter and draw off a few ounces of urine frequently, several times a day, we insert a cork in the catheter and pull the cork out at regular intervals, and draw off ten or fifteen ounces, enough to get the bladder gradually emptied, and by the time the bladder is entirely emptied it has taken about a week and the kidneys have been functioning freely, and we can then operate with the greatest degree of safety.

I may say one or two words as to my opinion of the so called two stage operation. I have always regretted doing a two stage operation. This operation consists in making a suprapubic opening, introducing a catheter, and draining the bladder as a preliminary to doing a radical removal of the prostate. Theoretically it sounds very fine, but, as a matter of fact, it does not work out in practice. The suprapubic wound generally becomes infected and a

horrible phlegmonous suppurating wound results. The bladder becomes adherent to all the points around it—adherent to the peritoneum, and when we come to enucleate the prostate, everything is found to be stiffened and united. There is no give to anything and we are liable to tear the peritoneum. The last time that I did a two stage prostatectomy (and I hope it will be the last time), I opened the bladder and drained it for two or three weeks. The wound in the abdomen became infected and the man was in very bad shape. Finally, he got a little better and I decided to take the prostate out. The bladder had contracted down very closely and was so small that there was no room to put my hand in to enucleate the prostate. The next evening they rang me up from the hospital, asking me to come down at once as the patient's intestines were all out. I went down and saw the patient, and, sure enough, there was a great coil of intestine lying on the abdomen. The patient had had an attack of vomiting and had blown his intestines out of the suprapubic wound, and one great coil was lying on the abdomen. The bladder was adherent to the peritoneum, everything was stiff, there was no elasticity, no resiliency, and the muscular force was sufficient to force the intestines out through the wound. I put them back, but after several days the patient died. Of course, there are cases which cannot be drained through a permanent catheter or cannot be drained through a perineal opening where a second stage operation must be done, but they are not nearly as common as people suppose, and the two stage operation is one to steer clear of as much as possible.

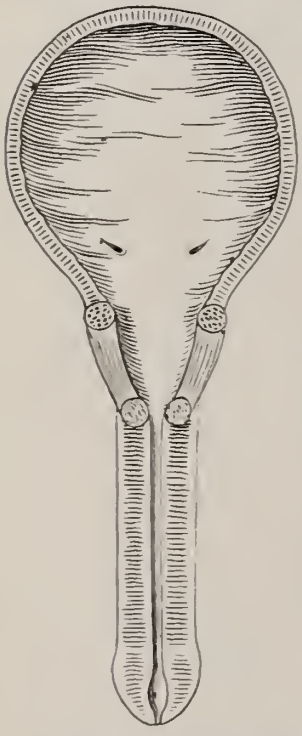

Fig. 4.—Funnel shaped outlet of bladder kept open by infiltration surrounding posterior urethra and causing postoperative urinary incontinence.

The great danger in prostatectomy is suppression of urine. The explanation is that the back pressure on the kidneys throws them into a state of congestion. This can best be guarded against by emptying the bladder gradually and keeping it empty with a retained catheter, bladder washing, forced water, and a protein free diet.

It takes from a week to a month to get a patient prepared for operation before it is safe to operate. We cannot hurry the process, and the degree of preoperative treatment makes for success or for failure.

As to the question of preliminary treatment, I might say that I have here some statistics which I heard at the Academy of Medicine. One hospital has a forty per cent. mortality rate in prostatectomies. Another hospital was cited as having a mortality rate of about ten per cent. About ten per cent. is the rate it should be. I take it that the hospitals having a forty per cent. mortality rate did not give patients preliminary treatment; they did not make use of the phthalein test; they did not acquaint themselves with the conditions under which the patients were to be operated upon; and they did not ascertain that the kidneys were in a state to stand operation. They simply took a man off the street and enucleated his prostate. On the other hand, where ordinarily careful, exact work was done there was a normal mortality rate of ten per cent. That is about right for a big hospital where they have to operate on everything.

Having gone through the preliminary treatment and with our patient in shape so that we think he can stand operation, the question arises as to the route to be chosen, suprapubic or perineal. Some men are wedded to one route and some to the other. A few years ago, we heard nothing but the perineal prostatectomy. Today we hear less of that and more of the suprapubic operation. The perineal operation is done now less frequently than formerly. To my mind, we ought to select the operation which is best fitted to the condition of the patient. If the prostate is situated high up, we put our finger into the rectum to touch the prostate, but finding that it is away up beyond reach of the examining finger, we know, therefore that the prostate is high up in the bladder. We cystoscope the patient and find a big middle lobe. We know it would be very difficult to take that type of prostate out by way of the perineum. The logical way of approaching such a prostate is by the suprapubic route, taking it out from above. On the other hand, given a prostate which is not very much enlarged, we are able, on introducing our finger into the rectum, to feel the prostate low down, and the best way to approach such

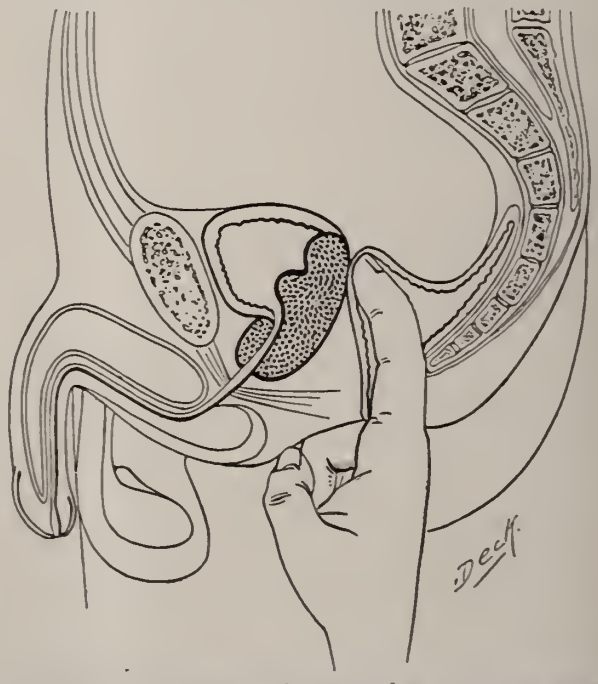

Fig. 5.—Senile hypertrophy of prostate; finger in rectum cannot reach upper margin of prostate; suprapubic prostatectomy is operation of choice.

a prostate is by the perineal route. To my mind, we make our decision actually on the anatomical conformation of the prostate. We know before operating which is the better route to choose.

The question of the anesthetic is important. It is essential not to drown old men with ether. It must of necessity be eliminated and passed out through the kidneys; they are more or less crippled, and the shock and additional weight of unnecessary ether thrown on them are liable to cause the kidneys to shut down. The ideal anesthetic for old men is gas-oxygen with a little ether. Ether, if carefully given in small quantities, can also be used safely as an anesthetic. I have done some cases under spinal anesthesia with stovaine, which, as a general thing, acts pretty well, although, personally, I prefer a general anesthetic.

The general aftertreatment of these cases is highly important. To avoid shock it is necessary immediately to put the patient into a hot bed with an electric baker, and the Murphy drip should be started at once to keep up the necessary fluid to fill the vessels and keep the kidneys going. Water should be forced by mouth as soon as the patient is able to swallow.

Each old man operated upon for an enlarged prostate has a different train of symptoms after the operation. It is a severe strain and they all suffer differently. Sometimes the kidneys seem to be at fault; sometimes the intestinal canal. Tympanites develops; they have vomiting and persistent hiccough. More seldom the heart plays out; they have feeble hearts, and that I think is the worst complication of all. Sometimes they become stupid and dull and the brain is at fault. Each of these complications must be treated accordingly. For the tympanites we use strychnine and eserine, hormonal, or pituitrin to stimulate the muscular fibres of the intestines. A high compound enema is useful in getting rid of the gas, and the old fashioned turpentine stupes still have their place and must not be forgotten. Hiccough is very troublesome, not so dangerous in its way, but annoying. In the presence of this complication, we stop the eserine and use an alkali and atropine. Hoffman's anodyne has also been recommended to stop hiccoughs, but I never saw a case where it worked. Blood pressure is a good thing also to keep track of. If it is too low we can push it up with strychnine, caffeine, or sparteine. Vomiting is a troublesome symptom afterward. Stomach lavage often gives relief for that.

The most dangerous symptom as a complication after prostatectomy is septic anuria. We can tell when that is coming on by the blowing up of the intestine: tympanites develops, the tongue gets dry and brown, the urine becomes scanty, the patient becomes drowsy and sleepy, and, unless we succeed in getting the kidneys going, the patient is "going out" from failure of his kidneys. The first thing that condition demands is the forcing of water, the Murphy drip, water by mouth, and the electric baker.

The medical aspects in these cases are so marked and so varied that it is always a very great comfort to me when I am so fortunate as to be associated with some medical man of broad experience to advise me about the diet and the various symptomatic conditions in these cases because the medical aspects require just as much attention as the surgical side of the case.

As to the care of the suprapubic wound, suprapubic prostatectomy has a higher mortality because the convalescence is slower. It takes from six to eight weeks for the wound to heal, and there is a great deal of attention required in the matter of the aftertreatment in cases operated in by this method. We use the silver wire sutures, which we leave in. A big Freyer tube is put in position to take care of the clots which form and carry them out. This is taken out on the fourth day. Then we make use of a rubber dam apron, to keep the patient dry. It is a rubber dam such as the dentists use. We cut a hole in the middle, smear the wound all around with zinc ointment, and stick that on with zinc ointment and place gauze here and hold this up so that the urine all runs out

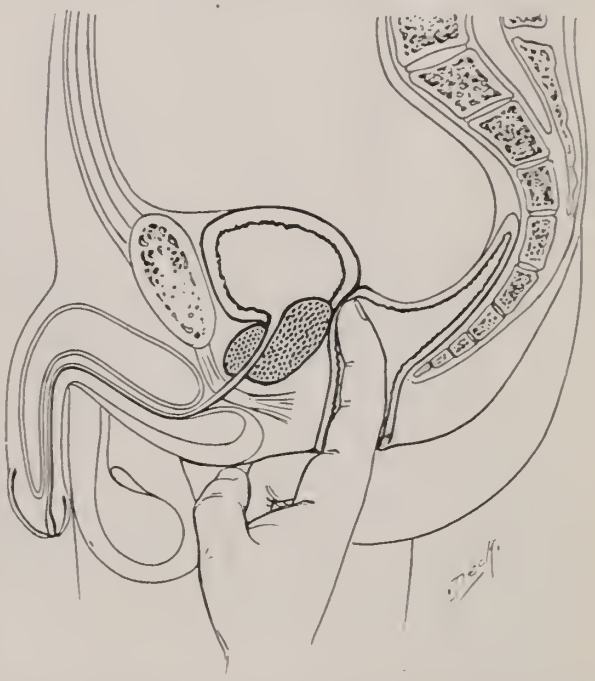

Fig. 6.—Senile hypertrophy of prostate; finger in rectum easily reaches and outlines upper margin of prostate; suitable for perineal intraurethral enucleation.

through the hole and is caught by the gauze and does not run all over everything, the dressings, bed, and clothes. The dressings are changed every three or four hours. It is a great comfort to these patients and they are able to be up and around after a fortnight.

In the perineal operation the aftercare is very simple. We put in a No. 34 French perineal drain which is taken out on the fifth day and the patient is able to be up and around at the end of a week.

As to the late complications, incontinence of urine is more common after perineal section than after suprapubic; in fact, after the suprapubic we very seldom find it, whereas after the perineal we find it quite frequently; it is an annoying complication. Examination with the water endoscope of Wossidlo discloses the reason. The posterior urethra is funnel shaped on account of the infiltration around it and the bladder sphincter cannot close the

upper segment, so that the cut off muscle is the only sphincter which is functioning. When this relaxes a few drops of urine dribble out. If the infiltration becomes entirely absorbed the sphincter of the bladder closes again and the dribbling ceases.

As to the cause of death after operation, suppression of urine heads the list. Shock is rarely the occasion of death and is taken care of by stimulation and the electric baker and the Murphy drip. Hemorrhage ought never to cause death. We use a suprapubic tampon and, if necessary, tampon the whole bladder. Hagner's bag I am not so sure about; it is liable to slip out of the prostatic cavity in the bladder and act as a foreign body, so I think it is better to tampon the cavity of the prostate with gauze.

Sometimes a patient will acquire a pulmonary embolism from a dislodgment of septic clots. Sometimes there is gangrene of the suprapubic wound and general sepsis, and occasionally a general and gradual failure of the vital powers is the cause of death.

Now, the results of our work in the Long Island College Hospital in the last three years have been as follows:

Forty-three patients have been operated upon for hypertrophied prostate. The ages ranged from fifty-seven to eighty-two years. Of these forty-three patients, six died. Two deaths were directly attributable to the operation; one man of seventy-seven years died of cardiac failure eleven days after the operation; the other was a man of seventy-six years with cardiac insufficiency. It was known beforehand and a grave prognosis was given. I said he would probably die, but the people were willing to take the risk and we operated, and he died about six days after the operation. One patient had poor renal function. There was an abscess of the prostate with increasing urosepsis, and the man died on the table before we finished with him. Another man had urosepsis in spite of three weeks' drainage, and we were operating by the suprapubic route when we found that the gut had prolapsed in front of the bladder. In opening the bladder, I incised the gut This was immediately repaired, but the patient died six hours later. One man died of carcinoma of the stomach four weeks after operation, and another man died of valvular disease of the heart six weeks after operation. So we may say that there were only four patients who died as a result of the operation, and as there were forty-three cases with four deaths, the mortality rate would be about ten per cent. That would represent a fair mortality rate where we have to operate on everything that comes along. If we could pick our cases and separate the good from the bad, operating in the good cases only, we could cut the mortality rate down to five per cent., or even less, but where we must operate in cases as they come and cannot turn them down, the mortality rate would probably be about ten per cent., which is a fair estimate. Where men of about sixty-five years in good condition, with good kidneys and a good heart, come in, with them we shall not have a ten per cent. mortality rate. It will probably be about two per cent., perhaps not even that much, but it is the old men with bad kidneys and urosepsis that bring the mortality rate up higher.

This, I think, represents the chief points in the matter of prostatectomy, and if due care is given to the details of preoperative and postoperative treatment, it makes very little difference what surgeon does the operation, or by what route or method the prostate is removed.

32 SCHERMERHORN STREET, BROOKLYN.

A CASE OF HYPOPITUITARISM.

By L. NAPOLEON BOSTON, A. M., M. D.,
Philadelphia,
Professor of Physical Diagnosis, Medico-Chirurgical College; Physician, Philadelphia General Hospital; Pathologist, Frankford Hospital.

The patient forming the subject of this report has twice been an inmate of the Philadelphia General Hospital, and upon his last entrance came under my care. He is an Italian, aged forty-nine years. His

FIG. 1.—Patient suffering from hypopituitarism. Hair absent from face and axilla; pubic hair covers triangular area as in the female, outline of face feminine, mammary glands resemble those of a young woman.

family record shows nothing of special interest; five brothers and five sisters are known to be living and in health. His past medical history is also wanting in instances of interest; he has suffered only from the diseases of childhood.

Social history. This patient arrived at the stage of puberty late in life, when probably seventeen or eighteen years of age. He did not, however, actu-

ally attain a stage of sexual maturity until after he was married, which was at the age of twenty-two years. During the first three years of his married life, three children were born, all of whom are now living. Following the birth of the third child, he came with his family to the United States, and since his arrival in this country, there have been born at full term, eight more children, all of whom died within the course of a few weeks. There were also several miscarriages.

This history would tend to suggest at least that hypopituitary cases do not as a rule produce healthy children. During his entire married life, sexual ambitions were of an extreme and somewhat perverted character. Questioning the patient shows very clearly that he was mentally unbalanced in this particular.

Medical condition. The heart is gradually increased in its transverse diameter. The first sound at the apex is replaced by a loud murmur, which is transmitted well into the left axilla. There is a decided accentuation of the cardiac sounds over the base of the heart.

Reflexes and sensations. Negative.

Physical examination. The general appearance of this man is so striking that it at once calls our attention to the existence of disease of the pituitary body. His skin is soft and has a velvetlike feel. His face is feminine in outline, and is without evidence of beard. There are but few hairs in the axillary regions (Fig. 1) and over the pubic area the distribution of the hair is typical of the female, the base of the triangular tuft of hair being directed upward (Fig. 1).

The mammary glands are decidedly enlarged, and in many respects resemble those of a young woman. The external genitalia, while actually masculine, show many characteristics simulating those of the female.

His hands present that striking appearance so commonly seen in disease of the pituitary gland, notably that the fingers are greatly shortened and display a peculiar stubby appearance, with deep cutaneous furrows surrounding each digit (Fig 2). In two cases of hypopituitarism reported in the NEW YORK MEDICAL JOURNAL for October 30, 1915, this characteristic feature of the hands was well exemplified. The finger nails are somewhat brittle, show a few longitudinal striations, and in general display evidence of malnutrition.

Special attention should be called to the peculiar condition of the skin in this case. The accompanying illustration (Fig. 3) is a photograph of a portion of the skin on the forearm. This extreme wrinkling of the skin has been present in two other cases of hypopituitarism that have come under my care, and it has also been observed by me in certain cases of diabetes mellitus. The wrinkled condition of the skin is so conspicuous in this case that when the patient rests his hand or arm upon any object, there are detected minute ridges traversing the skin at acute angles to one another, and between these thin elevations are seen corresponding depressions. The skin, while it resembles to some extent what is seen in old age, does not display the long folds characteristic of senility. Even in young subjects this appearance of the skin resembles that seen on the mucous surfaces of the stomachs of domestic animals. In this case this excessive folding of the skin is displayed not only over the arms but also over the chest (Fig. 4).

An x ray examination of the head shows the sella turcica to be appreciably enlarged. The clinoid processes approximate normal.

FIG. 2.—Hands characteristic of hypopituitarism; short, stubby fingers with deep cutaneous furrows surrounding each digit.

On November 30th, I directed the resident physician to give him 250 grams of glucose in fifty gram doses, one hour apart. Following the administration of the glucose, the urine was collected for twenty-four hours and examined for sugar with negative results. December 3, 1915, the feeding of glucose was repeated, with the exception that at this time, 400 grams were given within the course of about two hours. A careful study of the urine, following this second administration of glucose, showed it to be free from sugar. These two feeding experiments are, I take it, sufficient to prove that one feature of hypopituitarism, viz., an unusual tolerance for sugar, is present.

Fig. 3.—Photograph of skin of forearm, showing extreme and characteristic wrinkling of the skin.

Through the fact that this case simulated in certain respects cases that came under my care where glycosuria was present, with the assistance of Dr. L. W. Kohn, I have also made an examination of both the gastric and duodenal fluids, the latter of which shows changes that, so far as I am aware, have not been described in connection with hypopituitarism.

Fasting stomach contents. Amount, 35 c. c.; color, none; odor, putrid; consistence, mainly fluid; precipitate, flocculent, 15 c. c.; reaction, alkaline; free, hydrochloric acid, 0; total acid, 12; microscopic, epithelial cells (flat), salivary corpuscles+, myelin, mucus, débris.

Test breakfast contents. Amount, 70 c. c.; color, light green (bile tinge); odor, sour pap; consistence, mainly fluid and not viscid; precipitate, fine, well ground bread particles; free hydrochloric acid, 18; total acid, 60; rennin, 1:10+, 1:20+, 1:40+, 1:80+, 1:160+, 1:320+, iodine, amylum test=carbohydrate digestion good (interned products+).

Duodenal contents. Color, golden yellow; amount, 50 c. c.; reaction, neutral; consistence, viscid, mucoid, clear.

Test for diastatic activity (amylase). Dilution, one in 375=erythrodextrin+; one in 500=erythrodextrin+; one in 750=erythrodextrin+; one in 1,500=erythrodextrin+; one in 3,000=soluble starch; one in 6,000=soluble starch.

Test for tryptic activity. Dilution, one in 375=digestion of casein+; one in 500=digestion of casein+; one in 750=digestion of casein+; one in 1,500=digestion of casein+; one in 3,000=digestion of casein+; one in 6,000=digestion of casein+.

The fasting stomach upon examination gave evidence of the presence of a fair sized quantity of contents (thirty-five c. c.), otherwise nothing of interest. The test breakfast contents upon investigation also gave evidence of a fair sized quantity of contents (seventy c. c.). Although the quantity of the contents in each instance was not in excess, at least it seemed to rule out the possibility of hypermotility.

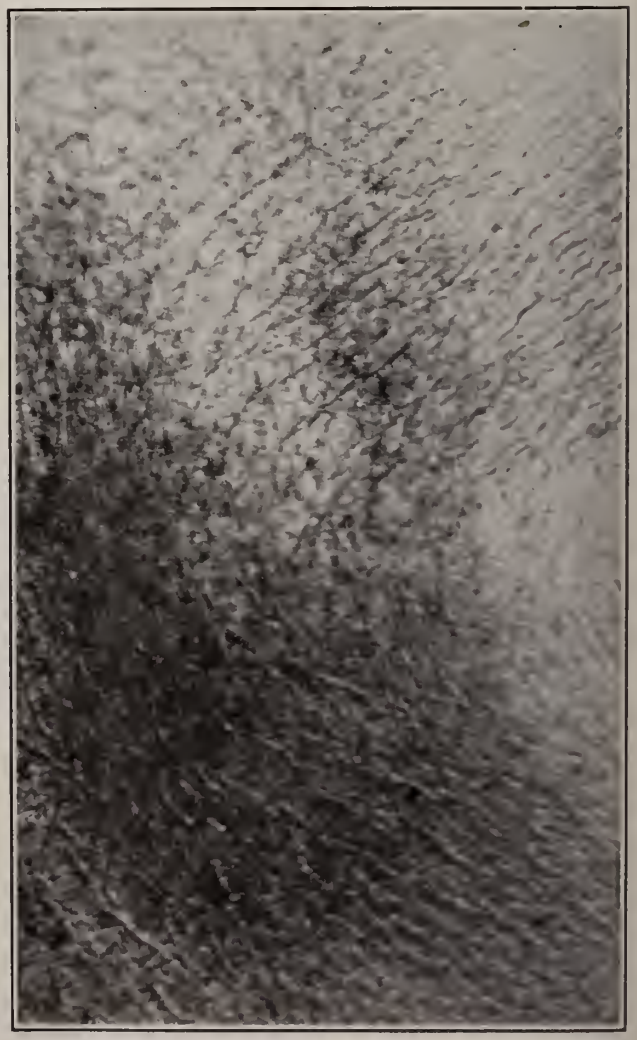

Fig. 4.—Photograph of chest, showing wrinkling of skin in hypopituitarism.

The acidity in this particular case approximates that in the part selected as within the bounds of normality. The gastric ferment activity, according to the degree of ferment and carbohydrates digestion, is very good. An examination of the

diastatic and tryptic activities of the duodenal contents shows the diastatic activity to approximate that ascribed to normal persons; while the tryptic activity was of high degree. The Wassermann reaction was negative.

1819 Chestnut Street.

QUARTZ LIGHT IN CUTANEOUS DISEASES.*

My Successful Experience Therewith,

By Edward Pisko, M. D.,
New York.

The reflection that up to fifteen years ago the treatment of the skin and its appendages was restricted to the employment of salves, pastes, lotions, and the like, is apt to evoke a smile of compassion. For a very long period the dermatological therapeutist was surrounded by a mist of empiricism. The dawn of a brighter era first appeared with the discovery of the Röntgen rays, the manifold usefulness of which has been demonstrated by clinicians throughout the civilized world. This was followed by the introduction of radium, the general employment of which, however, is largely limited because of its rarity and its excessive cost. Finally, the latest triumph to add to our weapons is phototherapy, and it is to this agency that I propose to confine my remarks.

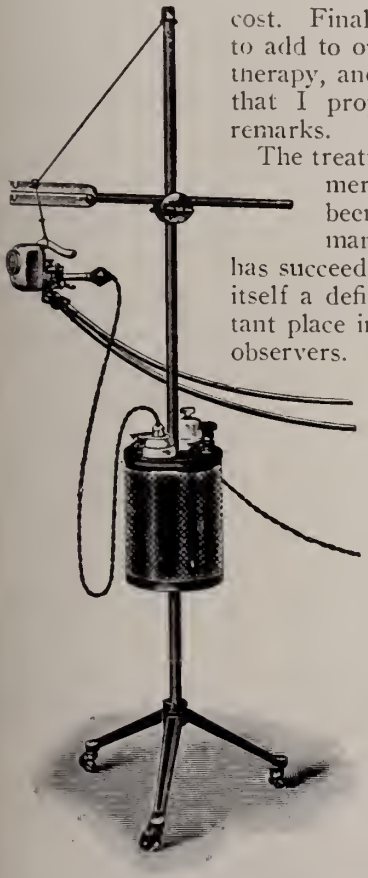

Fig. 1.—Kromayer Lamp.

The treatment by means of the mercury quartz lamp had been introduced in Germany some time ago, and has succeeded in establishing for itself a definite and even important place in the hands of a few observers. Yet, strange to say, even in the country of its birth, there still exists an astonishing degree of ignorance as to its nature and its uses. As early as 1907 Kromayer first published his experience with the lamp. He was followed by others, particularly Bach and Nagelschmidt. Notwithstanding their publications very little information exists, concerning the exact modus operandi of this lamp and its practical application in medicine. The quartz lamp is indicated in all skin affections in which there is a dilatation of the bloodvessels. The ultraviolet rays destroy the bacteria upon the skin, soothe the cutaneous nerve endings, cause pruritus to disappear. At the will of the physician, their action may be either superficial or deep.

Dr. A. Schuyler Clark was the first in this country to call attention to the subject by his publication of The Kromayer Lamp in the Treatment of Certain Diseases of the Skin (*Jour. of Cutan. Dis.*, June, 1914). In general my views are in hearty accord with those expressed in his paper, but I differ from him in that, according to my experience—and I wish to emphasize this, the lamp's utility is restricted to the treatment of small and circumscribed lesions, such as are of an area no larger than the aperture through which the rays emerge (Fig. 1). Conditions most amenable to such as are of an area no unculosis, folliculitis (simplex, barbæ, decalvans), acne vulgaris, and small patches of alopecia areata.

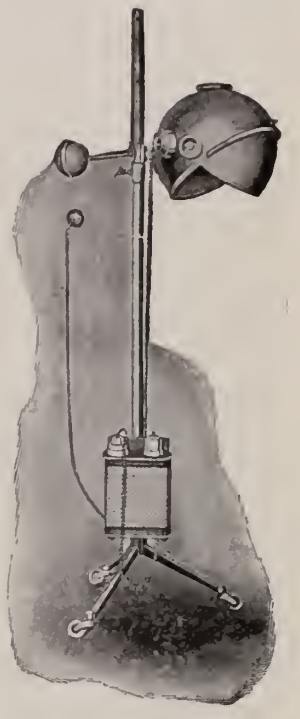

Fig. 2.—Bach-Nagelschmidt Lamp.

Another group of skin diseases can be influenced only by the deeper and more penetrating action of the rays. To this group belong: Lupus vulgaris, lupus erythematosus, nævus unius lateris, nævus vasculosus, nævus pigmentosus, and telangiectasis.

Increased penetration is effected by adding with pressure variously sized and shaped quartz crystals. The parts to be rayed are firmly pressed against the lamp by the attending physician and, to eliminate the heat rays as much as possible I interpose a blue quartz disc of five mm. thickness. This latter procedure at the same time enhances the efficiency of the exposure.

The results obtained in the above mentioned cases have been invariably excellent, even startling. Cosmetically this treatment is followed by less scarring than is obtained by methods hitherto employed.

The Kromayer lamp has been materially improved by the modifications introduced by Bach and Nagelschmidt, notably by the omission of the original cooling device (Fig. 2). This lamp is scarcely known in this country, the only reference to it having been made by Müller (*Medical Record*, May 8, 1915), who employs it exclusively in diseases of the scalp.

It is interesting to note the great difference in size of the ray emitting surface of the two lamps. Observe the comparatively very small aperture of the original Kromayer lamp, contrasted with the much larger ray surface and the great wealth of rays of the improved lamp. Naturally, the ray-producing quartz burner itself is much larger, and therefore its therapeutic effect is so much the

*Read before the Harlem Medical Association, April 15, 1916.

greater in the Bach-Nagelschmidt lamp. It is to this improved Bach-Nagelschmidt lamp I especially wish to call attention, chiefly because no mention of it is to be found in American literature. Both of these lamps are made in Newark, N. J.

The following remarks apply only to my experience with the Bach-Nagelschmidt lamp, which, quite appropriately has been named the Alpine Sun Lamp (*Künstliche Höhensonne*).

This lamp yields an enormous quantity of ultraviolet rays, the beneficial actions of which are applicable to a great variety of lesions of the skin. These rays are very soothing to the nerves, induce a delightful sensation of well being, and in capable hands may be employed freely with absolute safety to the patient and to the operator. Beside its striking local effect, the lamp appears to improve decidedly the general metabolic processes, to stop pain, increase appetite and sleep and, in consequence, maintain a gain in weight. Especial mention should be made of intractable itching, itching which persists for a very long time under other treatment and which promptly subsided after a few radiations, which, however, must be superficial, so as to prevent burning and blistering. A striking illustration of the great efficacy of the lamp is the following:

Case. Mr. B., kindly referred to me by Dr. G. M. Bennett, had suffered for eight years from a mycotic eczema of the foot, which had spread to its plantar surface. It had been treated with a variety of salves, pastes, lotions, and powders, as well as with the x rays. When I first saw the patient, his foot was covered with crusts and scabs and was oozing, and to make his lot bearable, it was necessary to keep his aching member swathed in bandages for eight long years. These were discarded after the fifth exposure. The eczema was completely cured, leaving a slight brownish pigmentation as the only evidence of his protracted suffering. In all other respects the skin became normal. The distressing itching disappeared after the third treatment, when I employed a twenty-five minutes' exposure at a distance of eighteen inches.

The first radiation was given at a distance of twenty inches and was of seven minutes' duration: this procedure should always be followed when instituting the treatment, in order to accustom the skin to the exposure. In the treatment of the face my experience has taught me to establish the rule that for the first radiation the exposure should be made at eighteen inches distance and be of four minutes' duration only. Apart from an agreeable sensation of warmth, the patients are not conscious of anything taking place—always provided that the eyes are protected by suitably colored glasses, such as dark automobile goggles. Quite obviously, the nearer the light rays and the longer the exposure, the greater is the action, as well as the sensation of warmth which ceases with the discontinuance of the raying. Four to six hours later, itching of a mild grade sets in, and the exposed parts of the skin become slightly sensitive to the touch.

Objectively, nothing is to be seen during the exposures, but three to four hours later there may be an erythema which lasts from three to four days. Should the treatment have been, say, of an hour's duration and at a distance of fifteen inches, it is likely to be followed by desquamation, which makes its appearance after about four days. Patients with thin skin are much more sensitive to the light than those with a generous panniculus adiposus.

I have had gratifying success in cases of leg ulcers, intertriginous eczema (especially in one case due to hyperidrosis), also in a case of Duehring's disease with intense itching and in cases of obstinate, chronic eczema which defied all other treatment. Particularly good fortune attended my efforts in the treatment of psoriasis, thus happily obviating recourse to the staining and evil smelling salves. At the utmost after five radiations the skin clears up and the disfiguring patches are quickly removed, leaving a slight brownish discoloration.

I am greatly pleased to report the most gratifying results with a class of cases hitherto the opprobrium of the profession and the despair of patients—namely, defluvium capillorum, premature baldness, dandruff, and a variety of conditions of the hairy scalp which render patients unhappy because of the repulsive sight they present.

In conclusion, I wish to state that although my experience with this lamp in skin diseases in general has been most gratifying, yet I wish again to emphasize my great confidence in the employment of the Bach-Nagelschmidt lamp in diseases of the scalp. It is especially in this class of diseases that we can look forward to absolute results, gratifying to both patients and doctor. Usually these patients traveled back and forth and in their despair wasted time and money upon quacks and charlatans; now this addition to the armamentarium of the dermatologist brightens our outlook for the cure of a malady less dangerous than distressing. My invariable successes cause me to pin my faith and hope to the Bach-Nagelschmidt lamp.

616 Madison Avenue.

THE SYMPTOM ATAXIA.

Its Successful Treatment.

By Heinrich F. Wolf, M. D.,
New York,
Chief, Department of Physical Therapy, Mount Sinai Hospital and Dispensary.

The greatest shortcoming in medicine, and the greatest obstacle to its progress, is the custom of identifying symptoms as diseases. Even now we find this mistake made very frequently. For instance, constipation is only a symptom, the word expresses merely the fact that the bowels do not move. The causes of this condition are many, yet the majority of physicians treat one case in the same way as another. This is only one instance, but we could multiply it manifold.

In this paper I wish to speak about locomotor ataxia. Ataxia is only a symptom. It was of great service to the therapy of this symptom when Maloney in his various papers pointed out that ataxia is not only dependent on certain pathological anatomical changes, but that psychological factors play an important role. I have treated patients with locomotor ataxia for nearly twenty years, with the Frankel method of reeducation. It was always a puzzle to me how differently the various patients

responded to the treatment, how patients whose disease was apparently a mild form, might not respond well, while severe cases might be greatly benefited. The explanation appears plainly, if we analyze these cases on the basis of Maloney's ideas.

The Fränkel treatment relies chiefly upon the assistance of the eyesight. It replaces the lack of sensation by control of the eyes. As the disease progresses it is quite natural that the patient becomes more self conscious, more highly strung, more, we may say, nervous. Everything that tends to lessen the patient's mental control, must interfere with his locomotion. The results therefore are neither satisfactory nor permanent, for the patient loses his control, when his orientation becomes more difficult, for instance, in strange places, in the presence of others, and in the dark.

We know now that ataxia may be caused by two factors which are usually combined; these are fear, and diminished sensations. If the treatment of ataxia is to be successful, we must analyze each case, so as to ascertain the role which these two factors respectively play, and we must regulate our treatment according to the findings of this analysis.

As an illustration. I present a case of locomotor ataxia which I have treated in the neurological department of Mount Sinai Hospital and report another case in a patient of Dr. Pearce Bailey's, which I have treated in my private practice.

Case I. J. G. did not admit infection; Wassermann 4 plus. Began to complain, April, 1915, of stiffness in the hands and difficulties in walking. September, 1915, after an injection, he got suddenly worse. Could not walk well. Legs grew steadily worse. Ataxia distinct for four months. Entered hospital, March 24th; walked then fairly well, but after another injection of salvarsan, the condition got so much worse that he could not walk or stand without great difficulty. There was some suspicion of general paresis. Examination revealed at once the fact that joint sensation was good, although he was unable to stand or walk. When I examined him, it could at once be seen that his muscles were in a state of high tension. In the first session it was impossible to bring about any degree of muscular relaxation. My treatment therefore consisted only in relaxation exercises.

The patient was blindfolded, and was then treated by the regular method, which has been described in various places. His progress was truly remarkable; this patient who was so highly ataxic, started to improve after the second or third treatment, and as I can demonstrate, can now walk so well that at times it is almost impossible to note the ataxia, and this even while the eyes are closed.

Case II. This patient, a girl of about twenty-seven years, became ataxic about eight years ago, not because of tabes, but because of arsenic poisoning. Tactile, as well as joint and muscle sensation, was practically gone. Seven years ago, I treated this patient with the Fränkel method of reeducation, and the result was that the patient could walk when the light allowed her to see. She walked with her legs widely separated; the gait was ataxic and she had frequent falls. The condition remained stationary for seven years.

Four months ago, I started with Maloney's method of reeducation. The patient relaxed very well and had no fear at all. Examination showed that joint sensation was almost entirely absent. She did not realize the position of her legs, and the hands were equally affected. To attempt to stand with closed eyes was hopeless. It was clear to me that in this case of ataxia, fear did not play an important part, and that the result of the treatment depended on the possibility of improving the sensation. On that basis I started with the treatment and the results were very encouraging.

I do not intend to go into the description of the methods employed, but only want to describe in short, the results. The joint sensation has improved very much, except in the ankle, where only excessive movements are perceived. The patient recognizes fairly well the position of her legs. She can stand for two minutes with closed eyes, and walk across the room, also with her eyes closed. It is now more than two months since she has fallen and she walks in the street without support.

These two cases seem to me to be illustrations of two of the principal factors in ataxia. They clearly show the necessity of analyzing every case of ataxia, and of regulating the treatment accordingly. They also show that when this is done, the results are so excellent that we are tempted to regard ataxia as merely a symptom which is eminently susceptible of improvement.

161 West Eighty-sixth Street.

DYSENTERY IN SERBIA.

By J. Rudis-Jicinsky, M. D.,
Chicago.

Uskup, the old Serbian capital of the great czar Dusan Silni—Dushan the Strong—the beautiful, but "old city in the new Serbian territory" freed from Turkish influences, while we worked there with our unit (1914-1915), had some nice broad streets, some of them tree framed, and others again so narrow, especially in the Turkish quarter, that, without proper sanitation and sewerage, there seemed to be constant danger! In the winter months, as stated before, we had an epidemic of typhus exanthematicus, febris recurrens, etc., pneumonia, diphtheria, scarlet fever, smallpox, measles, giant parotid abscesses, many cases of mastoiditis, otitis media, tuberculous glands, some cases of tetanus, and all kinds of infection with most repulsive cases, where the entire body of the wounded seemed to fill with pus, without apparent cause. There were many gunshot wounds, clean and infected, mostly compound fractures with constantly draining sinuses, and finally we had posttyphus gangrene and frozen extremities. In summer we had many patients suffering with dysentery in all forms, and had to be on our guard against the possible outbreak of cholera asiatica, plague, and similar diseases, which unhygienic conditions, overcrowding, and all kinds of insects may transfer from the unhealthy to the healthy, the louse playing the main role. In the two pavilions (bed capacity 435 and 310) of our hospital at the *Inzinirsky Kasarna*—barracks—upon a hill dominating the river Vardar, during the year of our stay we cared for 8,272 surgical cases and hundreds and hundreds from even the civilian population of the city and vicinity, including all the nationalities engaged in war without distinction. Sometimes not only was there an awful scarcity of good water for drinking purposes, but food was insufficient, the nourishment of the patients was not proper, and many suffered from the lack of good milk and vegetables, garlic, onions, and celery especially, scurvy developing in many instances. We had an opportunity to observe every variety of wounds inflicted by the modern instruments of war-

fare, but the description of these we shall reserve for some future article. I wish now to speak rather of the infectious inflammatory condition of the large intestine, characterized anatomically by ulceration of the mucosa, and clinically by frequent mucous and bloody discharges, tenesmus, fever, and prostration with abscess formation in the portal system, accompanied by anemia, in a word, the epidemic disease, dysentery, which occurred in Serbia and all our hospitals, summer and autumn, at any sudden change in temperature, the malarial districts suffering most. We had to deal with all the three distinct clinical types of this affection, each of which had the special etiological factors known to us from the times of Hippocrates, Galen, Sennertus, Morgani, Cruveille, Robitansky, Purkyne, Virchow, Lambl, Klebs, Thomayer, Zit, and others. They settled most of the questions connected with the disease, which appears nearly always during war. The ravages of dysentery in all the armies and among the suffering population of the stricken countries being usually great, our work was directed especially toward preventing the spread of the disease, as well as of all infectious diseases.

In the beginning, in Dzevdzelija (Gevgelija), Uskup, and later at different places in Montenegro, wherever our unit went, the patients would be put to bed in the condition in which they came from the trenches, in their clothing, dirty *charape*, shoes, boots, rags, mud, lice, and all. Thus the louse was everywhere, on the floors and even in the bandaging rooms, not to mention the discharges, slimy or bloody, in the dirty beds. There were so many patients and so many hundreds suffering with dysentery, and so little actual help, medical or other, before the American, English, and Russian missions came, that we had to evolve our own system of thorough cleaning, with careful search for the origin of the infection in typhus as well as in dysentery, in the water, milk, vegetable, and meat supply, sewage, drainage, etc. We had gauze instead of screens in the open windows, and we boiled the water right from the start and disinfected all discharges of the patients! One pavilion was used as a receiving and observation part of our hospital at Uskup. These wards, or *soby* as the Serbians called them, were under my charge, the bacteriological examinations and pathological specimens were made by me, our male nurses with the help of the Serbian *bolnichari* looking after the sanitation. My assistants had to separate the surgical cases from the medical and the contagious from the noncontagious, and take care to insure proper isolation, when necessary, and before we could send the contagious cases away to our tents, or to places managed by the English mission further away. We had only a few typhoid patients, but they were isolated just like typhus patients, with an abundance of fresh air in outdoor tenting, or if they were in the hospital, abundant ventilation in large airy rooms, cleaned and disinfected every day twice or oftener. The newly received patients were first recorded and then at once placed on a sheet, stripped of their clothing, their hair clipped, their beards shaved with a good rub down with petroleum, the head sprinkled with acetic acid, or naphthalin, if necessary. Then we gave them clean American pajamas, as received from Mr. Frothingham in New York, and placed the patients in a clean bed, the sheets covered with insect powder. Their clothing was marked, wrapped in the same sheet they had just lain upon, and sent to the steam sterilizer, and then to our tailor, who ironed the seams of the clothing to insure killing the louse eggs. After a patient had been under observation for a few days, he was assigned to his proper *soba*. The method was the same for sick or wounded, whole companies or soldiers, or prisoners of war, who came perhaps only for vaccination, or to receive their doses of combined cholera, typhoid, and paratyphoid serum, or antitetanic serum as a prophylactic in lacerated wounds.

In catarrhal dysentery the solitary follicles suffered most by hyperplasia, then sometimes a necrosis followed and ulceration, or we had purulent inflammation of the entire mucosa with superficial ulceration confined to the large intestine. Bacillus coli communis was found many times on microscopic examinations of the glairy stools, with red corpuscles, many leucocytes, and large oval epitheloid cells with fat globules, beside the bacteria of putrefaction or Cercomonas intestinalis. In bad cases we found shreds of mucous membrane before the stools changed to a greasy brown or dark green appearance, the discharges being less frequent and the blood diminished. In all our cases the characteristic symptoms, colicky pains followed by discharges from the bowel, were present, and in some cases the dejecta, with straining and tenesmus, appeared a hundred times a day or oftener. In milder cases, there would be at least six or ten movements for five days, showing mucus, blood, and pus in scybalous masses. The tongue had a greasy coating, moist at first, dry later and red. Anorexia was always present with excessive thirst, and sometimes even vomiting. The abdomen was flat and tense, the patient much debilitated, collapsing with small, frequent pulse, hoarse voice and hiccough, the temperature being only 103° or 104° F. For hiccough we gave ten drops of saturated solution of menthol in rectified spirits of wine or atropine hypodermically. The duration of mild cases was only about ten days, but the condition returned in many instances, in a more severe type, lasting four or five weeks, or became altogether chronic. In others profound prostration with serious nervous symptoms developed and the patient died from exhaustion, peritonitis, pericarditis, endocarditis, or pylephlebitis. This was seen particularly in soldiers wounded or enfeebled by operations, amputations, or disarticulations after gangrene, or in the aged *chichas* and *komitage*, the old volunteer Serbian soldiers and prisoners of war in their overcrowded barracks.

In other cases we found Amœba dysenteriæ, knowing that the patients, Greeks, Armenians, Turks, came from tropical regions perhaps. Amœba dysenteriæ is unicellular, motile, its protoplasm consisting of two zones, a colorless and a granular, with a visible nucleus and one or more vacuoles. We found the ameba in the discharges of the patients and traced the infection nearly always to drinking water. On microscopical examination there was

proliferation of the fixed connective tissue cells and amebas found in the walls and the base of the ulcers, in the lymph spaces, and sometimes even in the bloodvessels, but pus, so far as we know, was not detected. The lesions were always in the large intestine, and only once we found them in the ileum. The first visible changes with hyperemia of the mucosa we observed in the descending colon and rectum, then came the characteristic ulcer or necrotic process involving the overlying mucosa with its epithelium, the amebas reaching the submucosa in our opinion by infiltration through the destroyed and sloughing tissue. Sometimes this condition with numerous ulcers involved almost the entire mucosa of the large intestine, with fistulous channels between the ulcers. In healing, there was always plenty of fibrous tissue along the edges and the bases of the ulcers. Contractions followed, leading to stricture partial or irregular, as we saw in cases that came to autopsy, giving proof of diphtheritic inflammation secondary and terminal. In cases where hepatic or pulmonary abscesses developed, or pleurisy or peritonitis could be demonstrated, we found amebas even in the sputum of the patients. The affection was characterized by intermissions and more or less marked exacerbations of diarrhea, the liquid stools containing necrotic tissue of a grayish brown or yellowish gray color, with or without blood, the number of discharges per diem ranging from eight to ten. The prognosis was grave among the soldiers in the field, the mortality amounting in the beginning to eighty per cent., but in sporadic cases later on the danger to life was much less. The duration was eight to ten weeks.

We had also a few cases of diphtheritic dysentery or colonic inflammation accompanied by croupous or true diphtheritic exudation, some being primary and others secondary, but of acute onset with an initial chill, the fever rising rapidly, together with early prostration and delirium. Pain in the abdomen was severe, the discharges containing sloughs or tubular pieces of false membrane mixed with blood and mucus. The stools were dark brown in color with a fetid odor. Tenesmus was often present, the prognosis being then unfavorable. When recovery followed, the disease usually took on a chronic course. In some cases paraplegia occurred, the patients with wounds closed and apparently healed suffering the most, as each attack increased the liability to subsequent and stronger attacks.

We kept these patients in bed with the prophylactic measures mentioned above, giving milk, barley soup, and light meat broths, using our bouillon cubes during the active intestinal symptoms, though we gave easily digestible solids, eggs, plenty of well boiled rice, fish, fowl, and Serbian *Kyselo mleko* (sour or curdled milk, very rich, something like *kumyss* or *janina*) rice boiled in milk, etc., always in small quantities, gradually increased during convalescence. In asthenia and cardiac failure we administered cognac, *rakije*, or other alcoholic beverages, but in extreme cases of debility we gave strychnine. In nearly every case we gave castor oil from the start, or a saline purge to clean the bowel thoroughly, but not later on, depending on ipecacuanha and laudanum in small doses, repeated as often as possible. In tenesmus we used either opium suppositories or laudanum by enema, giving morphine hypodermically, if necessary. To tell the truth, we did not believe in many highly recommended intestinal antiseptics, depending rather on the vigorous employment of supportive measures, i. e., proper food and alcohol, especially in cases where the patient was used to it. We found this procedure much more important than the use of any medicament internally, since, as Anders says, "unfavorable cases tend naturally to asthenia and death, while favorable ones tend as certainly to recovery without energetic medical treatment." Antiseptic irrigation of the bowel we employed often, especially when the bowel was not irritable. In cases of pruritus ani, prolapsus, or extreme sensitiveness, we exposed the local lesion to the ultraviolet rays of the sun and proceeded to give our laudanum enema and starch water (or silver nitrate, tannic acid, salicylic acid, mercuric chloride alternately, each once a day), without cocaine suppositories or solution of cocaine. The injections were administered slowly, and the flow being interrupted at short intervals, they were tolerated nicely by the patients, who were in the dorsal position, or upon the left side with the hips well elevated. Locally, we employed dry heat only, treating various complications according to the symptoms, and remembering that the disease after an acute attack may, particularly if it is of amebic variety, change into the chronic form, lasting then for many months or even years. That we knew from the veterans of the Civil War in our own country, where the disease is far less frequent than formerly, owing to the advance made in hygiene and sanitary science, giving us an opportunity to fight some of the predisposing conditions more easily and more successfully.

We had to observe carefully all suspicious cases, had to examine all the cadavers, so that sources of contagion or infection could be discovered in time. The disinfection service was perfected later on, as far as possible, by means of directions printed in Serbian. Instruction was imparted to the people, and the members of the American, English, Russian, and French units and the Rockefeller Institute vaccinated everybody and cleaned up the whole country, cities and villages, and thus there was no anxiety concerning the health of the troops for a long time. The nursing of the dysentery cases progressed nicely, especially in the hands of our male nurses or those of the volunteer Serbian women, who attended either the Serbian or our school of instruction, which had been established in our tents during the most trying moments of the epidemic. Vegetables for our kitchen we cultivated in our own garden by the hospital.

THE PREEXISTING CONDITION OF THE INJURED.

A Medicolegal Study from the Standpoint of Employer's Liability and Accident Insurance,

By G. R. Doré, M. D.,
Bordeaux, France.

(*Continued from page 445.*)

The question of a preexisting arteriosclerosis acquires considerable importance from the fact of its near relation to traumatic neurasthenia, and I would particularly insist upon the fact that I have often observed, namely, the very slow return to normal of the intellectual functions after a trauma as an indication of a beginning arteriosclerosis. In truth, the coincidence of vascular disturbances and depressive mental troubles has been observed, and Krishaber has described the cardiac neurasthenic type which bears his name, but nobody has so strongly affirmed the close relationship between arteriosclerosis and neurasthenia, these two products of the arthritic diathesis, as Régis. The arteriosclerotic state, if not fully developed, but at least imminent, as it is in some arthritics, manifestly places the victim in a most favorable position of receptivity for the fruition and development of a serious and durable neurasthenia, accompanied by the organic signs of arteriosclerosis, aggravated or made evident by traumatic shock. In these patients, beside the nervous symptoms, we find circulatory disturbances, such as palpitation, tachycardia, angina pectoris, vasomotor disturbances, vertigo, tinnitus aurium, especially on the left and pollakiuria. One of the best means at our disposal for the diagnosis of traumatic neurasthenia, is the measure of the blood pressure, and I insist upon this point. Now, it is only a short way to go to conclude that these cardiovascular lesions, although latent, preexisted at the time of the injury. Such circulatory disturbances require as a substratum something else beside a purely functional state, and what could this better be than a preexisting lesion of the circulatory apparatus? This may perhaps not have manifested itself clinically, but in the larger number of cases it will have shown itself by symptoms that a medical man would not overlook.

Therefore, it seems to me unquestionable that very often the disturbances of the circulation are dependent upon a preexisting arteriosclerosis, that the trauma, no matter what it may be, is unable to explain. A trauma, however violent, is not enough to provoke a disease such as arteriosclerosis, but in a patient who is predisposed, although slightly, by his family origin or his own pathological past, a profound shaking up of the organism can, by the metabolic disturbances to which it gives rise, increase, favor, hasten, or even determine the lesions of arteriosclerosis long before their time is due. In its turn, toxoinfectious neurasthenia can very surely hasten the evolution of arteriosclerosis.

In his thesis (Bordeaux, 1906) Fauré records several typical cases of serious traumatic neurasthenia occurring in arteriosclerotic subjects, and clinical examination showed that in all there were vertigo, cephalalgia, tinnitus aurium, amblyopia, vibratory trembling, amnesia, insomnia, and asthenia, all neurasthenic phenomena coinciding with symptoms of arteriosclerosis, such as cardiac hypertrophy, exocardiac murmurs, varicose veins, tachycardia, and pigmented retinitis. Thus, behind the neurasthenia another disease appears distinctly, viz., arteriosclerosis. In only two cases recorded by Fauré was the trouble made clinically evident beforehand by distinct signs.

However this may be, it is difficult to admit that a traumatic shock could produce such an advanced sclerosis of the arteries as in the cases under consideration. To present the symptomatic picture of only its beginning, arteriosclerosis requires morbid processes which cannot be developed in the organism in a few days. It must have a soil prepared far back, either by the ancestors of the subject or by the subject himself, and this prepared soil, in imminence of arteriosclerosis, it needs only the occasion of a neurasthenizing traumatic shock to cause the disease to develop completely. It is clearly correct to suppose the preexisting arthritic state of the subject may be, after a traumatism, the reason for the appearance of neurasthenic phenomena. To conclude, if we take up the hierarchy of the causes in traumatic neurasthenia, we see that the predisposition is represented by a preexisting arteriosclerosis and plays an important part, certainly more considerable than that of the necessary efficient or determining causes. The nature of the necessary efficient causes is most difficult to determine in these cases. Perhaps it should be sought for in a special condition of the nervous system or in the problematical presence of special toxins, according to Bernheim's theory.

As to the determining part here played by the trauma, it is frequently of small import, particularly in elderly people, in which case its role is overshadowed by that of arteriosclerosis. What goes to prove this is that in young subjects traumatic neurasthenia is relatively mild when the state of their cardioarterial system allows them to pay the expenses of the perturbations produced by the traumatism. At all events, left to its own forces and without the intervention of a preexisting arteriosclerotic condition, the trauma is hardly capable of creating completely a serious traumatic neurasthenia. On the other hand, a trauma intercurrent upon a neurasthenia undoubtedly aggravates the latter. That this is so, is made made manifest by new symptoms or a recrudescence of those already existing, or by a more hasty evolution, which from torpid becomes galloping. Consequently, the idea, which, starting from this scientific viewpoint of the part played by arteriosclerosis, wishes to implant this notion in the juridical domain is, without any cavil, only one of justice. Unfortunately, it encounters from the start serious difficulties in its application. The scientific proof of an arteriosclerotic state presents all the difficulties of a retrospective diagnosis and the same causes of mistake.

It has been pointed out that if, in cerebral hemorrhage, we can resort to macroscopic and histological control in case of death, it is no longer the same when the subject survives, in which case we have simply the clinical evidence upon which to base our conclusions, which is, of course, much too little to establish certitude. I shall show later

on, when considering the forensic aspect, what can be deduced from the preexisting state of health in relation to arteriosclerosis.

I have referred to only a few of the disasters resulting from a preexisting arteriosclerosis and in so doing only the most characteristic have been selected. But they are far from being the only ones. Arteriosclerosis has been accused, justly or not I cannot say, of acting as a predisposing, or even an efficient cause in a host of diseases. Thus in a case recorded by Reinhold, the possible relationship was noted between cerebral arteriosclerosis and general paralysis, and it is known that a cerebrosclerous general pseudoparalysis has been described by some. In a case cited by Hochaus, calcification of the cerebral arteries has been suspected to be the cause of the epilepsy, while in an instance of relapsing anterior poliomyelitis, Oulmont and Blaudoin noted a tachycardia of 100, a systolic murmur from atheroma at the aortic orifice, and fifty cgm. of albumin, and they are inclined to believe that the arteriosclerosis may very likely have played a part in the evolution of the disease. Even hysteria has been considered as likely to arise from a cardiovascular lesion, since Potain related a case of hysterical paralysis in a subject affected by chronic aortitis with aortic dilatation, although it must be confessed that this pathogenesis is assuredly most questionable. If a trauma had occurred, we should not have failed to attribute the hysterical manifestations to it.

In the two groups of disease that have so far been considered, it has been shown that predisposition was, if not perfectly, at least distinctly defined, when the evidence of the necessary efficient conditions remained insufficient. Quite different is the case in tuberculosis. Here we can, it is true, define the conditions which make a person predisposed to tuberculosis, but these conditions are by no means absolute. There is also the question of soil, of organic mineralization, which comes in play, but quite differently from one subject to another. On the other hand, we know perfectly the necessary efficient factor which is Koch's bacillus, so that the etiological value of trauma is here reduced to the part of a determining cause as in the preceding affections. By itself, a trauma is incapable of producing the disease, and in order that it may develop at the seat of contusion a second factor must come into play, viz., Koch's bacillus, which was quietly dormant in the injured tissues. There consequently was a preexisting state, composed of one or several foci of tuberculous bacilli, since the infection could not come from without.

Under these circumstances, and this forms the first instance of a preexisting tuberculous state, the trauma plays an efficient part, revealing, as it does, the latent bacillary focus, whose development it provokes. It brings into activity a tuberculous process which could very well have remained for a long time, perhaps always in a latent state.

From the purely theoretical viewpoint, there does not exist, strictly speaking, a traumatic tuberculosis, therefore it clearly follows that under these circumstances the trauma is not clinically responsible, since it only revealed the presence of a latent tuberculous focus, but it is a question whether or not a distinction should be made between a so called revealing trauma and one that can very properly be termed a localizing trauma; in other words, the case in which the trauma provokes a localization of the disease at the point of the injury, the subject at the time carrying the disease with him, undergoing its evolution at some distance away, for example, a patient with pulmonary tuberculosis. It appears to me from the clinical standpoint that this case is identical with the preceding. Whether the presence of Koch's bacillus in the organism was latent, as in the case of a revealing trauma, or that it was already confirmed, as in the latter example, it still remains a fact that the bacillus of tuberculosis was already living in the organism. There is no difference between an unsuspected tuberculosis, but nevertheless existing as in the first case, and one in which the tuberculosis has been diagnosed. When the bacillus of tuberculosis is present in some tissue or organ of the body, far from or near the point of injury, is that alone quite sufficient for the trauma to cause a localization of the tuberculosis? Nägeli, of Zurich, was not able to find a single male cadaver over thirty years old exempt from tuberculosis, and in children Harbitz has shown that the lymph nodes, healthy in appearance, contained Koch's bacillus, for inoculation of the guineapig was positive. Therefore, the point of traumatism need not necessarily be tuberculized.

Clinically, it is quite permissible to suppose that the trauma does not localize the tuberculosis, but simply aggravates the already existing lesions. Broca is of the opinion that tuberculosis is never localized by a trauma and that there is merely a coincidence; the injury only aggravates and reveals a preexisting lesion. A sprain occurs at the time that there is some beginning stiffness or pain in a joint, and at once it is considered as the causal factor of the trouble, when on the contrary it is, perhaps, simply the effect of the disease. The frequency of latent tuberculosis is such that we can never affirm that a subject is not already the bearer of the infection, and, scientifically speaking, no state exists in which a trauma *per se* is sufficient to produce it. With the required conditions of the soil, in presence of the tuberculosis bacillus, a trauma merely reveals or localizes a latent tuberculosis. Now, although this action of the trauma is manifest only under certain conditions, its *aggravating action* on a tuberculosis in evolution is evident beyond a doubt. An injury to a part in which there is a preexisting lesion in a torpid state, hastens its evolution and suppuration rapidly takes place.

A trauma can also aggravate a tuberculosis by causing generalization, but this is probably infrequent and occurs only when the injury directly involves the diseased part. The vessels opened by the trauma may be invaded by the bacilli, the bacillosis becoming a bacillemia, the subject dying from an acute miliary process or a meningitis.

We now come to the question of predisposition from the forensic standpoint, and returning to the subject of predisposition in parasyphilitic affections, it is clearly evident that the predisposition consists in the existence of the syphilis. Now, by an approximate calculation of probability it is easy to prove that it is practically impossible to take into consideration this syphilitic predisposition. As was

pointed out, the proportion of syphilitics who later become general paralytics is two per cent. according to W. Mott, which, in other words, means that a syphilitic has one chance out of fifty of acquiring paresis. Consequently, the part played by a syphilitic predisposition represents only unity against forty-nine others of not becoming a paretic, so that even mathematically the predisposition is quite negligible.

Thus it would be a mistake to take syphilis into consideration from the forensic viewpoint as predisposing to parasyphilitic affection. The exact proportion of syphilitics who become tabetic is not known, but it may reasonably be supposed that it is about the same as in general paralysis, and the same reasoning may very properly be applied here. There are still other reasons which are opposed to the supposition that syphilis is taken into consideration in this affection. It is first the frequency of this etiology at the origin of these affections and, secondly and more particularly, the recent pathogenic hypothesis which advances that syphilis has not alone the power of creating a systematized myelitis because the common infections of the arachnoid cul-de-sac may create as much. Consequently, from both the medical and forensic viewpoints the part played by simple predisposition is, as far as a preexisting state is concerned, to be eliminated.

The same applies to diseases arising from arteriosclerosis for exactly the same reasons. All arteriosclerotics do not make their *exitus letalis* by a cerebral hemorrhage and the proportion of those having this complication following upon a trauma is about the same as that of persons not afflicted with arterial calcification, who after an injury suffer the same accidents. Now what of predisposition here? Clearly, a subject who, already arteriosclerotic, receives an injury, will acquire a much more serious traumatic neurasthenia than a young and healthy subject from the fact of his arteriosclerosis, so that in forensic matters it is only just to take this into consideration. On the other hand, proof of the arteriosclerosis is difficult, especially if necropsic or operative control is wanting and when we are compelled to resort only to laboratory or clinical investigations based on hypotheses which are at this very time still under discussion. Therefore, it would be difficult to convince a court and jury of matters which have not acquired scientific authority. In truth, it would be easy to invoke hardening of the arteries in a case of gangrene or cerebral hemorrhage following a trauma in order to reduce the importance of the injury from the forensic viewpoint, and all the more so because behind arteriosclerosis is often hidden that great arthritic diathesis, but the question of diathesis is not current money in legal medicine.

It is easily conceived how great is the difficulty to calculate accurately the importance of the part played by predisposition. The case of judgment rendered and reversed by the Court of Montpellier, France, is typical in this respect. The lower Court of Montpellier had rendered a decision on July 10, 1908, based on the experts' report, that the damages demanded on account of the trauma should be reduced in the case of a laborer, G., on account of the arteriosclerosis presented by the injured, esteeming that this had contributed to his fall and had aggravated the sequelæ. This decision was reversed on May 27, 1910, by the Court of Cassation, which handed down a decision in which the following remarks occur: "The morbid predispositions of the victim, whether they facilitated the accident or aggravated the sequelæ or not, are not to be taken into consideration in determining the amount of damages." It is true that, on June 18, 1908, the Court of Cassation had handed down a decision in another case that "it cannot be otherwise when the morbid predisposition is developed in the laborer, without any relation to the injury received."

In reality, it may well be asked upon what ground the experts and court saw fit to reduce the amount of damages asked for in this suit by sustaining the theory that the trauma resulting from a preexisting arteriosclerosis was not fully responsible for the condition of the plaintiff.

For all these reasons, viz., variability and the preeminently conditional character of predisposition and the great difficulty of giving a just appreciation of the part it plays, the expert will be the wiser if he leaves it entirely aside. Jurisprudence is unanimous in this respect and I will here give some examples of such instances.

D., a laborer, died suddenly while manipulating some iron weighing fifty kgm. At autopsy death was attributed to aortic insufficiency and provoked by alcoholic excesses. The three experts declared that the affection causing death was latent and conclusive. D. expired suddenly at the age of thirty-five years from a syncope having an aortic insufficiency as origin, and the work done by D. should be considered as an adjuvant cause of death. The decision of the court was "that from the conclusions so distinctly formulated, also taking into consideration that the law terms that there is an employer's liability when death is produced by work being done, no matter what may have been the morbid predisposition of the laborer, the court declares established the relation between cause and effect, between the work and accident followed by death, and admits the damages asked for by D.'s widow." (Civil Court of Cherbourg, January 18, 1911.)

A decision of the Court of Caen, July 27, 1911, confirmed the decision of the lower court on appeal: "Should be considered as having taking place during work, and consequently the act of April 9, 1898,[1] is here applicable, the accident, such as a fall, occurring on the place and during the time of working, although the cause has remained unknown; but it is not sufficiently demonstrated that the said accident was due to a morbid disposition of the victim or to a factor foreign to the work." (Court of Paris, May 16, 1911.)

"The employer is held liable by the terms of the law of 1898, for the consequences, even indirect, of an accident occurring during working hours and in the transaction of the business duties of the employee without taking into account the morbid predispositions of, nor the preexisting physical condition prior to the injury, etc." This was part of the ruling of the Court of Douai, February 14, 1912, in a case of amputation for rupture of an aneurysm.

[1] The Employer's Liability Act.

although the court admitted that the aneurysm was a preexisting morbid state, but that the victim should nevertheless recover damages because the cause leading to rupture was a slight blow received during work. I have referred to these decisions of the French courts simply to show how the law interprets such cases, but it is regrettable to observe how a simple predisposition is confounded with a manifest latent morbid state, such as aortic insufficiency or an aneurysm. It is nevertheless true that as far as parasyphilitic or arteriosclerotic affections are concerned, predisposition cannot enter into account, and we will now consider if the same applies to tuberculosis, and if, in absence of predisposition, we can consider as a preexisting morbid state the necessary efficient cause, viz., Koch's bacillus.

It has been pointed out from the scientific standpoint that a trauma, in the case of a posttraumatic bacillosis, only acts by fixing the bacilli preexisting in the organism, but nothing proves that, without the trauma, these very bacilli might not have remained indefinitely latent. Thus, in France at least, all the decisions completely neglect the question of a tuberculous predisposition, likewise the possible presence in a latent state of the causal agent of tuberculosis in the organism of the injured, basing the decisions on the principle that there is a relation between cause and effect, between the injury and morbid manifestations following it, there is no ground for considering the predisposition of the victim to the lesions resulting from the injury. For instance, in a case of Pott's disease following upon a strain, the Court of Montpellier (November 3, 1905) awarded full damages. A laborer with a tuberculous knee joint (white swelling) received an injury to this knee with the result that amputation was required, and the Court of Rennes (July 18, 1906) allowed damages in full, although the existence of the tuberculous bacilli prior to the injury was evident, but was not taken into consideration by the trial court.

To sum up what has been said of the question of predisposition from the forensic standpoint, I believe that it should be rejected, and the same applies to the presence of the causal agent in the tissues prior to the injury. Consequently the preexisting physical state in the above mentioned class of cases is to be put aside.

The question of the preexisting physical state changes its aspect when, instead of predisposition or efficient causes, we are dealing with diseases fully developed prior to the receipt of the injury, and which have been influenced by an intercurrent trauma. Here also there are various problems to be considered, which I will examine successively. The first case is that of some real but latent disease and retrospectively recognized by interrogation of the patient, as in the case of the tabetic woman in whose antecedents paroxysms of pain characteristic of tabes in full evolution, were discovered. This case offers some interesting considerations. This woman was not capable of simulation since the accident was not one where a suit for damages could be brought. However, it was only by a minute interrogatory that this symptom which she had forgotten, could be brought to light in her antecedents.

In all cases, even where there is no action for damages in view, and the patient's assertions are devoid of suspicion, it is practically impossible to arrive at an exact conclusion as to the date a myelopathy or a cerebropathy began. When the subject begins to notice functional disturbances, it is probable that the affection made its beginning long before. The clinical commencement follows too soon upon the receipt of the injury, and there is a maximum of probability that the disease has been suddenly revealed by the injury, when in reality it existed in a latent state for an indefinite time. From the strictly forensic viewpoint, in the case where the disease is real but latent, the injury cannot with equity be considered responsible for the trouble.

It is to be distinctly understood that the notion of a disease in full development prior to the injury is applicable only to affections whose evolution and duration are fairly well known and understood, and where we may approximately fix the beginning even by a retrospective examination. This does not apply to diseases with an indefinite evolution, such as arteriosclerosis for example. It may possibly find its application in cancer, which affection I have purposely avoided when considering predisposition, for the very good reason that we are in complete ignorance as to the conditions which predispose to this affection. This much having been said, we will next endeavor to formulate the forensic rules to be followed in cases where the injured having an organic myelopathy, cerebropathy, or tuberculosis, attributes his affliction to an injury received.

When the personal inquiry of the expert reveals the presence of undoubted symptoms of the disease in question prior to the injury, the problem is reduced to a study of whether or not there is a revelation or simply an aggravation of the disease. What at first sight would seem relatively easy is, in reality, quite a delicate matter, because the symptom which for the patient reveals the trouble, is merely one of an aggravating kind for the medical man, and, moreover, a condition of affairs which cannot fail to result in a conflict of ideas. Take the case of a *revealing traumatism*. It is just here that above all intervenes the importance that should be attached to the retrospective value of the trauma in the affection in question. The relative importance of the prior state of health and trauma is, in point of fact, most variable. Sometimes, the prior state of health plays so preponderating a part in the evolution of the affection, that it can alone be invoked and the effect of the trauma is occasionally so intangible from this viewpoint, that it is necessary carefully to weigh the pros and cons in order to avoid considering it as a cause, when it really is a pretext or a revealing agent. Then again, the prior state of health is the only reason for the working incapacity. The simplest case is that where, playing an undoubted revealing part, the trauma occurs in an early tabes which is ignored by the patient, and produces a fracture, when in a healthy subject a trauma of the same intensity would have resulted merely in a simple contusion. In this case the injury is the revealing agent, since the tabes was undergoing its evolution insidiously without as yet giving rise to incapacity for work.

All depends upon the clinical analysis and the con-

ditions in which the injury occurred. The expert must look for and estimate the nature and violence of the shock, its direction, and the occupation of the subject at the time of the accident, the position of his limbs, and all other details susceptible of enlightening his convictions. If it can be shown that the fracture was produced by an insignificant trauma, and if the cause was manifestly unable to produce a fracture in a healthy subject, the preexisting tabes should be considered, however paradoxical it may be, as a simple predisposition. There are, consequently, certain well defined cases in which, considering the insignificance of the efficient cause, a more or less latent preexisting morbid state may very well be considered as a simple predisposition and, from this standpoint, to open no way for a decrease in the amount of liability. But—and it is a point to which I would particularly call attention because it seems to me a new conception of this particular point of the question of the preexisting state—it is not the entire tabes that should be recompensed by the payment of damages for a single paroxysm of fulgurant pain produced by the trauma, nor for the latent tuberculosis existing prior to the receipt of the injury which may only have caused a simple hemoptysis resulting from the effects of an effort on the part of the plaintiff during work. There is here an important disproportion between the resulting symptom and the entire preexisting latent disease, so that the causal responsibility must lose its integrity, to limit itself strictly to the resulting symptom, without which the case would end in evident injustice. There is, to my mind, no difficulty in fixing the ultimate limits of the resulting symptom, and there can be no possible doubt of the relation of cause and effect with the trauma. If after a period of temporary incapacity, instead of evolving toward recovery, the symptom continues without any end in view, we come back into the following case, namely, that of aggravation. As to doubt relative to the bonds of causality between the resulting symptom and the trauma, it is for the expert to establish solidly this fact; and, if scientific proof is lacking we may rightfully admit the relation juridically, on the simple succession of time. The case in point frequently arises in instances of locomotor ataxia, because Gauraud was able to collect twenty reports of intercurrent trauma in tabes, and of these twelve might have been, or were accidents involving the employer's lability. It is curious to note that singly, some symptoms are more particularly influenced by trauma than others, particularly exacerbations of painful phenomena.

The trauma may either exaggerate the already existing symptoms of locomotor ataxia or provoke the appearance of a new symptom with such rapidity that the relation of cause to effect cannot be doubted. This case will be examined shortly. Thus, there is too much tendency to profit by the fact that a trauma by provoking the appearance of a new symptom of some affection, reveals the existence of this very disease, in order to place upon the injury all the responsibility of producing the malady *in toto*.

I am unacquainted with any legal decision relative to the revealing part played in tabes by a trauma, but I am glad to be able to quote a judgment handed down by the Civil Chamber of the Court of Cassation on April 5, 1909, which states that "there are no damages due if the death results from a latent morbid state, where the trauma only plays the part of the revealing agent." The trauma must be the direct revealing agent of the prexisting physical state and not indirectly so, as a decision rendered on November 24, 1910, by the Civil Court of Toulouse appears to uphold, as the Court says: "It is not sufficient to show that a sprain, by preventing the patient from taking nourishment, has thus permitted organic defects to reveal themselves."

I know of no case where tuberculosis has been revealed by an hemoptysis having by itself produced only a temporary incapacity for work.

We now come to the question of *aggravating* trauma. In practice, as we have already seen, this and the preceding case are not infrequently combined. It is the symptom provoked that keeps up, as, for example, an hemoptysis which takes the place of the signs of cavities or a paroxysm of fulgurant pains preceding incoordination. There are many ways in which a given disease may become aggravated, either spontaneously or by the fact of an injury. The simplest is the appearance of some new symptom, or what comes to about the same thing, in the reappearance of a former symptom which had disappeared. In order to be able to judge an aggravation which has really occurred in the preexisting physical condition from an injury, it is essential, 1, to know exactly this prexisting morbid state, and, 2, to be certain that without the injury the preexisting state of health would not have become spontaneously aggravated from the very fact of its evolution; in other words, that the new symptom observed need not necessarily occur in the given disease. For example, it cannot be said that motor incoordination will surely come on in a tabetic who as yet is free from it, any more than trophic disturbances, if an external cause does not occur to favor their production.

However, Thoinot declares that in every case of progressively evolving tabes, and counting motor incoordination as one of its symptoms, a time will come when this, slight as it may yet be, will by the progress of the affection, become at length manifest to everybody. This, of course, naturally happens without any trauma coming into play in the majority of tabetics, so that we should be rather skeptical when a trauma is invoked as a cause of the incoordination. In this objection, it will be observed that Thoinot absolutely ignores the question of the date of appearance of the incoordination and that, if the patient suddenly arrives at the maximum of this incoordination immediately after the receipt of the injury, it is quite a different matter than if it took ten years or so before it appeared.

The same cannot be said of a new localization of tuberculosis following an injury, because, even admitting the presence of foci of bacilli at the point of injury, the correlation of the spot traumatized implicates the trauma as the causative factor of the new localization. In this case the trauma should, both medically and legally, be considered alone responsible for the new symptom considered with its individual prognosis as well, and not by the general health of the subject, as it results from the combination of the new symptom with the preexisting morbid state. The only problem to settle

is whether or not the new symptom would have made its appearance without the action of the trauma. It is clear that it would be unjust to consider complete working incapacity, which is usually that of most tabetics, as due entirely to the injury which in a tabetic has only set up another symptom of the disease. This distinction, to my mind, is much more in conformity with equity.

Beside the new symptom, properly speaking, is to be placed a former symptom which reappears. Thus, subjects afflicted with infantile paralysis are sometimes in adult age, taken with late amyotrophy. The etiological value of trauma in myelopathic amyotrophies has given rise to important writings from the pens of Kurt Mendel, Pagenstecher, Sand, Ladame, and Inglbraus. Rémond has recorded the following case: The patient, thirty-three years of age, who had been an infantile paralytic, received within six years two violent injuries of the shoulder, and six years after the first trauma an amyotrophy of the scapulohumeral type developed. The awakening of the amyotrophy may occur twenty or even fifty years after the attack of poliomyelitis.

To explain the elective localization in the anterior horns at the time of the first attack of the affection, it is generally admitted that it results from a congenital predisposition of the cord due to hemorrhage as well as to hereditary predisposition. Thus, it is clear that the latter predisposition cannot be solely responsible. Certain cicatricial sequelæ, the remains of the first attack, certainly intervene in the genesis of late amyotrophy. We can here readily recognize the origin of the preexisting state; the amyotrophic state which is both visible and palpable, where predisposition is certain since the subject is already diseased, and on the other hand, the hereditary and constitutional medullary debility. But how often infantile paralysis will again progress later on in life without the action of trauma, and how many cases, too, remain stationary, even after the receipt of an injury!

The reappearance of an old infantile paralysis cannot be considered as a latent state from the forensic viewpoint as may be readily conceived, but simply as a suspended state which equals an indefinite predisposition, much less active than that created by syphilis in regard to parasyphilitic affections, and not preventing the subject from earning a living. Then by analogy with what we have learned as to the appearance of a really new symptom, trauma, it seems to me, should alone be held responsible in this case for the development of this symptom whose reappearance it provoked.

In spite of its bad prognosis, tuberculosis cannot be considered as a disease of progressive evolution on account of the frequency of its remissions. Two cases are to be considered, according to whether the injured person was already in such a state of health that his working capacity was compromised; or a trauma inflicted on a subject who, although tuberculous, enjoyed full working capacity. In the first case, the working capacity will be still further decreased, the affection is hastened in its progress, or the term of the affection may be advanced, but the trauma has here played merely an accessory part in a subject who must of necessity die sooner or later, so that it is quite impossible to hold the injury entirely responsible for the outcome. Others, however, hold the contrary view. It is clearly the duty of the expert to collect all possible data relating to the patient's antecedents, and in his report he must indicate the amount of working incapacity resulting and the state of health prior to the receipt of the injury. The rest is for the court and jury to decide.

A number of cases reported in the literature show the manifestly aggravating action of trauma upon malignant tumors, particularly in their evolution, be the trauma surgical or simply accidental. On the other hand, cancer represents an eminently progressive pathological process. This fact should be impressed upon the court by the expert. In the courts of Europe I think I may safely say that in the present state of forensic law they would admit the influence of the injury only when the preexisting disease was not in a clinically advanced state, or was not likely to result in the hastened or early death of the subject from the nature or situation of the neoplasm. It devolves upon the expert clearly to explain all the elements of a given case with detail and precision.

To conclude, it may be said that the etiological value of the trauma in the cases considered in this paper occupies only a secondary place in the etiological combination composed of predisposition, the necessary efficient cause, and the determining factor, and in some cases it is even doubtful if the injury alone can produce the given affection *in toto*. The trauma, more particularly, provokes the consequences of the preexisting state.

From the forensic viewpoint, it is the duty of the court to determine the actual part played by the trauma. The expert, in his report, should state what he has actually discovered, without taking into consideration what may be the opinion of the court. The preexisting latent morbid condition should always be systematically searched for as soon as there is any doubt as to the reality of the effects of the trauma, and an obvious pathological condition should at once reduce the part played by the trauma to one of aggravation only.

A TEST FOR SYPHILIS.

Mercury Bichloride in the Blood Serum and Cerebrospinal Fluid.

By George B. Ubel, M. D.,
Ithaca, N. Y.

The principles of this test are based upon a few of the recognized facts in chemistry relating to the action of colloids, viz., first, that bacteria react in accordance with all the established facts pertaining to colloids; secondly, one colloid may be absorbed by another colloid, preventing its precipitation when a mild precipitant is added. By assuming that normally there is a colloid present in the blood serum which is not present in the cerebrospinal fluid, the test may be satisfactorily explained.

The addition of a one in 100 solution of mercury bichloride to the nonsyphilitic blood serum will precipitate the colloid which is normally present, and a turbidity will result, but if the serum is syphilitic the colloid of Spirochæta pallida protects or absorbs

the colloid normally present in the blood serum, and hence the serum remains clear when the precipitant is added.

The reaction on the spinal fluid is just the reverse, i. e., normally there is no colloid present, hence when the bichloride solution is added no precipitate is formed, but in a syphilitic spinal fluid the colloid of the spirochete is present and is precipitated by the solution.

TECHNIC.

The technic is the one described by Doctor Gordon, of Philadelphia, in the New York Medical Journal for February 20, 1915, though he made no attempt to explain the principle of the reaction. To several c. c. of clear serum, in a clean test tube five to ten drops of a one in 100 mercury bichloride solution is added. If the serum is nonsyphilitic, a white, flocculent precipitate will be formed, giving the serum a turbid appearance in from a few seconds to three minutes, and, if allowed to stand several hours the precipitate will settle to the bottom of the test tube. On the other hand, if the serum is syphilitic it will remain clear.

The technic for testing the spinal fluid is the same as for testing the blood serum, but the results are reversed, i. e., a nonsyphilitic spinal fluid remains clear and the syphilitic spinal fluid becomes turbid when the solution is added.

The blood should be withdrawn four or five hours after a meal, as this insures a serum free from chyle, and therefore much clearer. A clear spinal fluid is also imperative, hence the test should not be attempted on a blood tinged fluid.

This test was tried out on the following series of unselected cases in the neurological wards of the Erie County Hospital, Buffalo, N. Y.

		Wassermann.			Globulin	Bichloride test.	
	History.	Serum.	Spinal fluid.	Cell count.	on spinal fluid.	Serum.	Spinal fluid.
Case 1*....	+	+	+	38	+	+	+
Case 2.....	+	+	+	48	+	+	+

Case 12***.	—	—	—	18	+	—	+
Case 13....	—	—	—	6	—	—	—
Case 14....	—	—	—		—	—	—

Case I. First test showed both blood and spinal fluid positive for syphilis. One week after two injections of salicylate of mercury, one grain, the blood became negative, but the spinal fluid remained positive.

Case III. History was positive for syphilis, but patient had undergone strenuous antisyphilitic treatment, and one year previously had had a negative Wassermann.

Case XII. Woman, aged fifty-four years, history negative; epileptic seizures developed within the last six months. Before a second sample was taken, the patient became maniacal, and was transferred to the State hospital for the insane.

This series of cases is reported with the permission of Dr. George A. Sloan, attending neurologist, Erie County Hospital, Buffalo, N. Y.

REMARKS.

The small number of cases reported does not warrant us to draw definite conclusions, but it is interesting to note that in Case I the blood serum became negative after antisyphilitic treatment had been started, also in Case XII a positive mercury bichloride test was obtained, while the Wassermann reaction was negative.

DRUG ADDICTION.

A Study Made in Essex County Prison and House of Detention,

By Edward W. Markens, M. D.,
Newark, N. J.

About the morphine and opium habit much has been written and a goodly amount of literature prepared. More especially is this true since the enforcement of the Harrison narcotic law.

Statistics given by the various contributors on this subject invariably lay stress on the history, when it is a conceded fact this class of patients are most unreliable in their statements. How then are we to arrive at the facts unless we have the patients under close observation and know positively that they do not receive drugs other than those prescribed?

There is no desire on my part to compare the method employed here with others better known, my only purpose being to give a résumé of the results obtained and let the reader draw his own conclusions.

I have taken the last seventy cases of drug addiction for the purpose. It must be borne in mind that these cases were treated at the Essex County Prison at Newark, and we must be mindful of the fact that every patient was under restraint and subject to the treatment prescribed. The cases included patients addicted to one or more drugs, cocaine, morphine, heroine, and opium.

The duration of the habit was from three months in the case of a morphine addict, to twenty-one years of opium smoking. The ages were from twenty-one to forty-five years.

The patient, when received, must take a bath and is thoroughly examined, and then placed in the hospital. Most careful observation is made for the first twelve hours, and the patient's condition indicates the amount of drug he is to receive.

The average first daily dose given is one and a half grain of morphine (morphine being the only drug prescribed, regardless of the fact that many patients are suffering from the effects of other drugs). The dose is reduced according to the condition of the patient, sometimes a quarter grain a day or perhaps the same amount in two or three days. On rare occasions it was found necessary to increase the dose a quarter grain for a day or two. The treatment in this series of cases extended from five to twenty-eight days.

A standard dose as in some of the well known treatments is not desirable, as each patient must receive individual symptomatic treatment.

Purgation is not resorted to, except in rare cases, when gastric lavage is also employed.

The regular prison fare is given three times a day.

During the first twenty-four hours the patients

suffer from nervousness, insomnia, anorexia, nausea, and rarely, vomiting. Pains in the lower extremities are noticeable in every case.

In every case the patient was off the drug for at least ten days before being discharged, and in many cases for three or four weeks. Very little ill effects were experienced after the first twenty-four hours, and in every case a gain in weight was noticeable.

It might be well to state here that we have a most admirable hospital in the prison where these patients are treated. Everything is bright and cheerful; there are good baths, plenty of sunshine, and fresh air in abundance. The bedding is changed daily and the bed is of the highest standard. The average patient coming under our care, it must be remembered, is the poor unfortunate without friends and at best with poor abode. The conditions we have to offer him are in such strong contrast to what he has been enjoying that he instantly realizes he is among those who will help him to better things.

The new patient is invariably encouraged by seeing the good results obtained by others. In this manner the unfortunate is led to help himself, which is a large factor in the treatment of this class of patients.

Of course, there is no way for us to tell how lasting is the effect this treatment may have; suffice it to say that a fair percentage when discharged will write from time to time, and tell how well they are doing and how they have not returned to the habit.

If we have been instrumental in permanently curing even a small percentage of the people, our work is well done. Time alone will tell.

RECOVERY FROM TETANUS.

By B. Scheinkman, M. D.,
New York.

The following case of tetanus with complete recovery may be of some interest to the profession, especially from a therapeutic point of view:

Case. On May 10, 1916, I was called to see Mike C., twenty-eight years old, a laborer at a city dumping dock. He complained of pain and stiffness in the lower jaw, dryness in the throat, and weakness in the legs. Gave a history of a severe chill about two days before. On examination I found the inferior maxilla quite rigid, both sternomastoid muscles somewhat contracted with deep depressions in the supraclavicular and infraclavicular spaces, and marked weakness in the lower extremities. Pulse slightly accelerated, no fever, no inflammatory process in the throat, no swellings in either the submaxillary or other glands in the region. On further examination, I found a small scar on the palm of left hand, the result of an apparently slight abrasion which had healed about three months before and was quite forgotten. I became suspicious of tetanus, but left the patient untreated for further developments till next day.

On May 11th, I found the patient much worse; lower jaw much stiffer and more painful, sternomastoids considerably more rigid, supraclavicular and infraclavicular spaces more sunken, lower extremities much weaker; walked with great difficulty and with somewhat of an ataxic gait. My diagnosis of tetanus having thus become more convincing, I called Dr. Thomas Rehling in consultation, who, on thorough examination, fully coincided with my diagnosis. Patient having absolutely refused to go to a hospital, I injected him with 6,000 units of tetanus antitoxin subcutaneously the same day.

On May 12th, patient's symptoms much aggravated; lower jaw firmly set; muscles of neck, abdomen, and lower extremities contracted and rigid, head retracted, with the corners of the mouth drawn up, imparting to the face a peculiar, ghastly expression with a sardonic grin. I injected 10,000 antitoxin units more—intramuscularly.

On May 13th, patient's condition worse; severe tonic contraction of all muscles of back, abdomen, and legs, closely simulating rigor mortis. Injected 10,000 units of antitoxin.

May 14th, patient in a state of complete opisthotonos with severe and frequent clonic convulsions of all the muscles, each spasm accompanied by an agonizing moan or groan; body covered with perspiration and patient presenting a moribund appearance. I injected 10,000 units antitoxin and simultaneously injected also five c. c. of a two per cent. solution of carbolic acid.

May 15th, patient in same condition. I injected six c. c. of the carbolic acid solution, and prescribed a powder consisting of quinine sulphate two grains, phenacetin, antipyrin, and caffeine citrate, of each one and one half grain, and codeine grain one fifteenth, with instructions that this dose be given every two hours. Antitoxin abandoned. The combination of synergists I have been in the habit of prescribing in most of the infectious diseases in the course of my professional practice and close observation with results so gratifying as to give me ample justification to consider quinine as possessing either direct germicidal powers or stimulating phagocytic properties or both; while the well known antipyretic, analgesic, and antispasmodic effects of antipyrin, phenacetin, and caffeine are, in my opinion, undoubtedly due to their exerting some important vasomotor influences favoring elimination of morbid material from the system; as shown by their powerful control over temperature, pain spasm, urinary secretion, perspiration, etc., which control would be difficult to explain in any other way, since these drugs are neither anesthetics nor narcotics. The depressing effects of phenacetin and antipyrin (as is the case with most of the coal tar products) being counteracted or neutralized by the stimulating effects of the quinine and caffeine, renders the simultaneous administration of the drugs absolutely safe for any reasonable length of time according to indications.

May 16th, patient's condition unchanged. Injected seven c. c. carbolic acid solution, same powders continued. May 17th, 18th, 19th, 20th, patient's condition practically unchanged. Treatment the same, except for a daily increase in the carbolic acid solution by 0.5 c. c. May 21st, 22nd, 23rd, 24th, patient showed slight, but progressive improvement. May 25th, marked general relaxation of muscular rigidity, jaws open about one half inch. Same treatment continued. May 26th, 27th, 28th, progressive improvement. Treatment continued. May 29th, opisthotonos almost disappeared, clonic convulsions ceased, abdomen lost the boardlike hardness, patient free from pain, could move legs. Same treatment continued.

May 30th, June 1st, 2nd, 3rd, 4th, patient fully relaxed, could open jaws to almost full extent, sardonic grin disappeared, looked cheerful, had good appetite, discontinued all treatments.

June 8th, patient fully recovered.

As a noteworthy feature, I consider the fact that during the entire course of the disease the patient's temperature never reached above 101° F., and only on very few occasions the pulse showed some erratic tendencies, but not enough to require interference. The intellect remained unimpaired throughout the entire attack.

During the whole period of the disease, the patient was fed on milk and copious quantities of water (owing to severe thirst), which were given by mouth, notwithstanding the firm closure of the jaws, thanks to a narrow interspace between the upper and lower incisor teeth (a fortunate anatomical anomaly), through which he could be made to sip his liquid food and medicine.

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

THE RELATION OF DIET TO DISEASES OF THE SKIN.

By Albert Strickler, M. D.,
Philadelphia,
Assistant Dermatologist, Philadelphia General and Samaritan Hospitals; Lecturer in Dermatology, Temple University Medical School; Etc.

Food, a prime necessity to the maintenance of human existence, is at the same time capable of producing a varied number of pathological conditions in the human body. These conditions may be either acute or chronic.

Foods are capable of acting either as primary or as secondary factors in producing disease in a number of ways.

1. We may partake of a certain type of food for a long period of time and so upset the equilibrium existing in the body.

2. We may partake of food which acts as an acute poison, producing various acute diseases of the skin.

3. The human organism may be hypersensitive to various proteins, and the ingestion of these particular protein foods may be productive either directly or indirectly of diseases of the skin.

4. The bacterial flora of the intestines may so alter the products of digestion or be altered by them, as to produce toxic products whose absorption may induce various cutaneous eruptions.

A great many affections of the skin have at one time or another been attributed to errors of diet; we shall discuss, however, only those diseases in which foods as a causative role have been definitely established. These diseases are psoriasis, eczema, urticaria, and acne vulgaris.

Psoriasis—This disease which constitutes between four and five per cent. of all skin diseases, has remained an enigma until recently. Various theories have been advanced to explain its pathogenicity, but none have met with approval.

Recent studies by Dr. Jay F. Schamberg, Dr. John A. Kolmer, and Dr. G. W. Raiziss have thrown some light on the nature of the disease. As a result of carefully conducted metabolic experiments, carried out on psoriatic subjects over varying periods of time, the following facts were demonstrated:

1. On a given protein diet a psoriatic subject eliminates less nitrogen in the urine than a normal subject on a similar diet.

2. Psoriatic patients show a marked retention of nitrogen, and this occurs on a diet low in nitrogen, and on which a normal person would fail to maintain an equilibrium.

3. A low nitrogen diet has a most favorable influence upon the eruption of psoriasis, particularly if it is extensive. The authors maintain that severe cases of psoriasis improve under such diet, almost to a point of disappearance of the eruption. From these studies and also from some observations of the author, it may be concluded that in a large number of subjects of psoriasis, particularly those who can be kept in a hospital where the diet is carefully controlled, a low protein diet influences favorably the eruption of psoriasis and probably renders local remedies more efficient by making the skin less irritable.

Eczema—This disease, the most common of all affections of the skin, is of variable etiology. For a long time, diet was suspected to be causative of a certain percentage of cases of eczema. In recent years attempts have been made to separate cases due to diet from those of different origin. This is done by means of anaphylactic food tests. Two principal methods are employed:

1. The cutaneous method, consisting in abrading the skin and rubbing in the various food products, waiting thirty minutes and reading the reaction; and, 2, the endermic method, which consists in injecting into the layers of the epidermis a stated quantity of the different proteins in solution or suspension, waiting from twenty-four to forty-eight hours, and reading the reactions. All agree that a positive reaction consists primarily of a papule at the site of injection and secondarily of an erythema. All agree that normal persons do not give positive reactions.

These food reactions in eczema have been studied by Doctor White, Doctor Blackfan, and the author.

Doctor White employed the endermic method, using a dental burr to produce the skin abrasion, then rubbing in the various food proteins. He concludes that approximately twenty per cent. of patients with eczema do not react positively to food proteins as shown by the anaphylactic tests. He reports some fifty-six cases in which these tests were carried out and a number of cures due entirely or in part at least to a modification of diet. Doctor White used local treatment as well as a dietary régime based on anaphylactic food tests.

Doctor Blackfan studied forty-three patients without eczema, using the anaphylactic food tests, and only one gave a positive test. His work was done with children. Of the twenty-seven with eczema, twenty-two gave evidence of susceptibility to proteins. Blackfan found the endermic method more sensitive than the dermic. Removal of some proteins in older children and adults, brings about great improvement in some cases of eczema. According to this author, in infants it is not successful because of the inability of regulating their diet. It is next to impossible to remove all proteins from the baby's rations without seemingly undermining the health of the baby.

In my investigations I employed the endermic method in all cases. In all, forty-six patients with eczema were studied and a great majority of them were adults and older children. Our plan has been, whenever feasible, to withhold local treatment completely to see what benefit diet exerted on the course of the eruption both as to its subjective and objective phenomena. In this study it was found

that fifty per cent. of our patients were benefited to a greater or less degree by a changed diet as shown by the anaphylactic food tests. In twenty-six per cent. the food tests were entirely negative, while in the remainder the correction of diet, as shown by the anaphylactic food tests, did not have any bearing on the course of the disease.

From a review of the literature and from our own work, it may be concluded that eczema in a certain percentage of instances, is benefited by a correction of diet, based on anaphylactic food tests, and that this method constitutes a valuable addition to our armamentarium in treating eczema.

Urticaria—While it has been known that acute urticaria is due in the largest number of instances to the ingestion of certain foods such as pork, sausage, fruit, strawberries, shellfish, etc., and these facts are substantiated by the food tests, still these tests applied in chronic urticaria do not yield satisfactory results. The author studied a number of cases of chronic urticaria, and while some positive results were obtained, a correction of diet according to these findings failed to influence the eruption.

Acne vulgaris—Lastly, we consider acne vulgaris a disease which afflicts between seven and ten per cent. of the patients in private dermatological practice. Anaphylactic food tests in this disease, even when positive, do not yield fruitful therapeutic results when the diet is corrected according to the findings.

According to studies conducted by Doctor Kolmer, Doctor Schamberg, and the author, in this disease we are dealing among other things with an intestinal toxemia. Both complement fixation experiments and therapeutic results seem to point strongly in this direction.

SUMMARY.

From this brief exposition the following may be summarized:

1. In psoriasis we are dealing with a disease of disturbed nitrogen metabolism. In this disease there is a marked nitrogen retention; and when the patient is placed on a low protein diet, particularly when the eruption is extensive, the disease is influenced very favorably.

2. In eczema, in about fifty per cent. of the cases, a correction of diet as shown by the anaphylactic food tests, is productive of good therapeutic results. In fact, these should be made in every case of chronic eczema, because physicians of experience realize the difficulties in treating this group of cases.

3. In acute urticaria, the anaphylactic food tests are of value from the viewpoint of both prophylaxis and therapeutics, while in chronic urticaria, their value is questionable.

4. In acne vulgaris there is evidence in most cases of an intestinal toxemia, as shown by the complement fixation tests, and food sensitization does not play a role in the etiology of this affection.

Value of Oysters.—Stutzer maintains that it takes fourteen oysters to contain as much nourishment as one egg, and 223 to equal a pound of beef. Their cost is triple that of beef.

Bacteria in Oysters.—Gigon and Richet, Jr. (*Bulletin de l'Académie de médecine*, June 27, 1916) report a bacteriological investigation of samples of oysters bought in Marseilles, France. Analysis of the juice of oysters revealed an average of 2,814,000 aerobic organisms in each oyster, with numerous putrefactive organisms and colon bacilli, and in one instance each the A and the B paratyphoid organism. Study of different parts of the oyster showed them to be all infected, the juice containing 443,000 colon bacilli to the litre, the intestinal mass, 130,000, and the pallium 90,000. The danger of infection arises not only in the proximity of oyster banks to drainage outlets—a condition insufficiently controlled in the Marseilles district—but in the character of the water in which the oysters are kept immediately before sale. Analysis of the water of the old port of Marseilles, in which many unsold oysters are kept from one day to the next, contains 6,000 to 8,000 colon bacilli to the litre. Observations such as these demonstrate the absolute necessity of proper supervision of the site of oyster beds by the authorities.

Influence of Diet on Development and Health of the Teeth.—Jay I. Durand (*Journal A. M. A.*, Aug. 19, 1916) points out that there is a steadily increasing tendency of the teeth of civilized races to decay which has been proved by extensive comparative observations. At the present time caries is to be found in from eighty-six to ninety-five per cent. of the school children and is common even in very young children. That diet has much to do with this prevalence of caries is shown by comparative studies of children fed in different ways for the first six months of life. Those fed exclusively at the breast showed caries in about forty per cent.; fed upon cow's milk mixtures in about the same proportion; while those fed on sweetened condensed milk showed caries in about seventy per cent. These facts show the importance of a properly balanced diet during infancy if the teeth are to be preserved. Such a diet should be a properly modified cow's milk with the early addition of vegetables, fruits, and meat if the infant cannot be nursed by the mother. The vegetables, fruits, and meats may be started as early as the sixth month if properly prepared and controlled. The next important point comes in providing a diet for the early years of life which will teach the proper function of the jaws and develop them. Children should be given strips of tough meat, from which to extract the juice by chewing, and such foods as bacon rind, tough crusts, hard dry bread, apples, celery, lettuce, etc., should be included in the dietary to develop the jaws and teeth. Later the prevention of decay should be practised by the institution of proper sequence in the dietary. The last article in each meal should be one which will not leave a sticky carbohydrate residue to cause decay. Such a residue cannot be removed by the tooth brush. The meal should end with meat, green salad, celery, radish, apple, orange, or fibrous food in general. Acid fruits are ideal for the close of a meal, as they provoke the secretion of a highly alkaline saliva with high ptyalin content.

Diet in Ulcer of the Stomach.—Charles Greenberg (*Medical Herald,* July, 1916) advises that the diet should consist of three ounces of a mixture of milk and cream every hour from 7 a. m. to 7 p. m. for the first few days; then to add slowly soft boiled eggs and well cooked cereals until by the tenth day three eggs are taken daily and a three ounce feeding of the cereal with the milk mixture. Cream soups may be substituted, but the total bulk of any single feeding should not exceed six ounces. This diet is intended to nourish the patient and to control the acidity, and in some cases the feedings can be given only every two, three, or four hours. By the fourth week the intervals between feedings may be slowly lengthened, so that the interval becomes every two hours in the fifth week and later every three hours. Combined with this plan of feeding we may use the two following powders alternately, given midway between the feedings:

I.

℞ Magnesii oxidi ponderosi, }
Sodii bicarbonatis, ... } .....āā 0.6.
M. et fac tales chartulas.

II.

℞ Bismuthi subcarbonatis, ...0.6;
Sodii bicarbonatis, ...1.5.
M. et fac tales chartulas.

After a period of use of these powders they may be discontinued and teaspoonful doses of bismuth may be taken before breakfast each day for six to eight weeks, washed down with a glass of water. For a year or more the diet should consist of milk, cream, cereals, soft eggs, vegetable purees, soups, and bread and butter. Healing should not be assumed until the patient has remained free from ulcer symptoms for six months after a return to normal diet. The rigid diet may be reinstituted if discomfort returns despite careful management, but this is usually an indication of some complication.

Digestibility and Utilization of Egg Proteins.—Bateman (*Jour. Biological Chemistry,* August, 1916) shows very plainly the necessity of investigating routine methods. For many years it has been the custom to feed patients on raw eggs in order to increase the body weight. As long ago as 1898 Steinitz reported that the administration of raw egg white to dogs caused vomiting and diarrhea. This was again noted by Mendel in 1913. Bateman found that when uncooked egg white of three to five eggs was fed to dogs it invariably caused diarrhea of more or less severity. Experiments were also made with raw eggs upon a number of persons, and the results obtained confirmed what had already been determined. The egg white was poorly utilized, and most of the patients suffered from diarrhea which, however, generally decreased in the course of several days. Various investigators report that fifty per cent. only of the raw egg albumin is made use of.

As a control experiment two sets of dogs were fed meals alike except that one received native egg white ground to a fine pulp. By the addition of water to both types, meals were made as nearly of the same consistence as possible. Those meals containing the raw food stuffs always caused diarrhea while the others did not.

It has also been noted that the ingestion of raw egg white does not stimulate the flow of gastric juice, that it quickly passes out of the stomach accompanied by scanty amounts of gastric juice and that it is practically unaffected by pepsin. In other words there is to all intents and purposes no gastric digestion.

In order that egg white be made digestible, it must be coagulated by heat; by precipitation with alcohol, chloroform, or ether; by incubation with dilute alkalies or acids; by partial digestion by pepsin; by conversion into alkali metaprotein.

The conclusion of greatest interest to the clinician is that although whole eggs, raw egg white, and albumin water are extensively prescribed, there appears to be little in their conduct as food stuffs to warrant much faith in their nutritive value or ease of assimilation.

Contemporary Comment

Medical Misocainia or Neophobia.—The popular man and the man of true originality, according to the *Medical Standard* for August, 1916, are seldom one and the same individual. Reasons are obvious enough. The popular man stands on your own level, or not more than a hair's breadth higher; he shows us the truth which we can see without shifting our present intellectual position. This is convenient. The original man, on the other hand, stands above us; he wishes to wrench us from our fixtures, and to elevate us to a higher and clearer level. But to quit our old fixtures, especially if we have sat in them with comfort for a long time, is no such easy business; accordingly, we demur, we resist, we even give battle, and while we may suspect that he is above us, we try to persuade ourselves (laziness and vanity earnestly assenting) that he is below us.

But now let a speaker of the other class come forward—one of those men that have the opinion which all men have. No sooner does he speak than all of us feel as if we had been wishing to speak that very thing, as if we ourselves might have spoken it; and forthwith sounds from the whole world a celebration of that surprising feat. What clearness, brilliancy, justness, penetration! Who can doubt that this man is right, doubtless he is a clever man, and his praise will long be in all the magazines.

These ideas have been given expression by Carlyle, but Carlyle might carry them a great deal further if he had studied the history of misocainia, or the hatred of new ideas, in medicine. The essential motives of misocainia are prejudice, selfishness and indolence, the archenemies of all progress, and there are cases on record in the history of medicine in which misocainia had developed to such a degree that men of science, of exalted position, lost the sense of truth and honor and degraded themselves by the employment of unworthy means in order to suppress a new idea and descended to intrigue against those who had promulgated a new truth.

NEW YORK, SATURDAY, SEPTEMBER 9, 1916.

A PSEUDOSCIENTIFIC HOAX.

It seems that our English cousins have their own troubles with the patent medicines, the fakers, and the garbled newspaper reports of medical matters. A leading London newspaper, according to the *British Medical Journal* for March 18th, published recently an elaborate account of a complex method by which the blind were to be educated to perceive objects by means of light rays reflected on their chests. A wealth of detail was given, well calculated to impress the lay reader, although the least informed practitioner could see at a glance that the possibility of any such contrivance ever being of the slightest use to the blind was so exceedingly remote as to be negligible.

Newspaper hoaxes have been plentiful before and since the immortal one of Edgar Allan Poe, which reminds us that the recently deceased poet Riley perpetrated a poem supposed to be a posthumous one of Poe's, which was so like the latter's in style as to deceive many literary critics until Riley confessed. Such fakes as these, together with the wires from out of town correspondents recording the bad boy who fed whiskey to the chickens and the consequent discovery of a rum omelet in the nest, are all harmless enough and make sufficiently light reading for the heated term, but a story such as that referred to by our English contemporary should be regarded somewhat differently. The better sort of newspaper is still prone to publish medical news without sufficient discrimination. When we consider that a large group of any newspaper's readers have no means of checking up these statements and that these readers are precisely the victims of itinerant quacks, the responsibility of the lay press becomes evident.

Obviously, the newspaper may rejoin that it cannot afford to pay a medical expert, that it must get its news items from customary sources, and that it is its policy to print anything which may interest its readers, provided only that it is not indecent or libelous. By dint of a little trouble, however, there is no doubt that the newspapers of any community could arrange with the local medical society to supervise items of this sort. The arrangement would be mutually advantageous and an argument in its favor is the fact that the average daily paper does not consider material of this kind very important, but rather in the nature of "feature stuff" and "fillers," to be kept on the editor's desk until needed to fill a gap. We must except our New York newspapers from criticism of this kind, as they are generally careful to verify news of a medical or surgical nature.

APPLICATION OF THE BINET TESTS.

Sufficient interest has been aroused and a sufficient amount of work has been done with the Binet-Simon scale for measuring intelligence, and with its many modifications, to reach the conclusion that the limitations of these methods are too great, and the results obtained by many equally good observers too varied, for their use as absolute gauges of mental development. The scale idea is a good one, and an ideal to be aimed at. There should be scales for mind as well as for body; but while the readings might be comparatively easy, the interpretations would always be difficult. Naturally, because of the complexity of the mental processes and the meagreness of our knowledge, they must be elastic to be embracing. Commensurate with this elasticity, the interpretations of readings or results must be more liberal. Hasty conclusions in respect either to diagnosis or to the best disposition to be made of a subject found defective may cause a great deal of harm. Because of the tendency to carry on mental measurements on a large scale, as in the school

systems, for segregation purposes, or for special training, special liberality of interpretation is required, else the percentage of error will be so large as to vitiate the whole endeavor.

In so complex an organization as the mind the influences affecting its development and its action are so varied that any rule of thumb becomes a guide and not an index. Physical condition, environment, nourishment, temperament, health, and race, all exert a marked influence on the mind. Persons apparently defective, at least according to the scale, will often be found to make remarkable improvements when such factors are detected and remedied. No new mental centres are developed or new brain cells vitalized. The stimulus to mental development is the general stimulus that all body processes get through the general removal of adverse conditions. It is for this reason that no mental examination or mental survey can logically be undertaken unless preceded by a thorough physical examination and a painstaking inquiry into modifying conditions.

European observers working with school children of different countries, but with the same scale, found that children of equivalent ages and school grades gave widely different results. This is significant when it is considered that a scale retardation of from two to four years is sufficient to relegate such a child to the class of the permanently retarded. The differences certainly cannot be explained on the ground that there is a difference in mental development in different countries; it is explained on the natural variability and the difference in point of view. Differences of this kind become more marked in the requirements for the tests of the higher ages (Haberman, *Journal A. M. A.*, July 31, 1915). Indeed, observers in this country have found wide differences, not only in different children, but in the same children at various but proximate occasions.

Moreover, the tests have the highest value in the lower ages. It is a moot question whether they have any value at all above the age of twelve years. The test questions for the lower years are questions of orientation fundamental in scope, and required for the proper test of a child almost everywhere. The questions for the higher years are not for the determination of intelligence and discernment, but rather of the powers of expression. The tests given for the ages between twelve and sixteen years are rarely answered, even by higher students and teachers, as the scale makers intended them to be answered. Because the questions for the lower years are fundamental is the reason why great variation in the same class of children is proof of fundamental differences in mental development, of so profound a nature that the subjects who vary from the standard must have definite mental defects. Even variations which are much above the standard for that class of children, as in the precocious, is significant of an "instable" and too highly matured, and, therefore, easily disturbed mental organization. The term "exceptional child" is a term comprehensive enough to include marked variations above as well as below the standard. For the higher ages the range of mental development is very great and of necessity is varied in conformity with individual needs and individual station. It is well nigh impossible to embrace all angles within the confines of a measuring scale; the limitations are many and hard to grasp. Special mental capacities crop up, and some are abandoned in behalf of others. In other words, mental specialization is normally a later year development. Specialization in the early years denotes deficiency in many faculties, the remaining energies being all launched in the patent faculty. The specialist of later years is the rule of the normal; the specialist of the younger years is the rule of the defective. It can be seen how unwieldy a scale that attempted to encompass later year variations would be. The test of later year mental capacity is rather a test of ability and usefulness in chosen life work, and above all the progress made in such work. It is the test of the ability to contribute something to society.

The newer Binet modifications must, moreover, have a new aim. The generally defective are easily found. If the specially defective accidentally finds his proper sphere, the fact that some of his faculties are defective is of no moment. The aim should be to find out the defective faculties, determine the extent of the normal ones and train the individual definitely with a view to place him in his proper sphere and not to allow this placement to be subject to the vagaries of accident. This is very much a field for applied psychology. Binet has opened a new field rather than devised a new method, and his work calls attention to the necessity of searching out all the defective. The work requires the cooperation of the sciences of medicine, psychology, pedagogy, and sociology; no one of these is entirely sufficient.

THE DIAGNOSIS OF SYPHILITIC SUBOCCIPITAL OSTEITIS.

The diagnosis of syphilitic suboccipital osteitis, on account of its extreme infrequency compared with tuberculous lesions and certain types of rheumatism, is often a matter of some difficulty. The more or less advanced age of the patient, however, his specific antecedents, and the presence perhaps, of some gross or minute luetic manifestation, should arouse the attention of the physician when in pres-

ence of a painful stiffness of the neck, usually spontaneous from the beginning and increased by rest in bed. A sharp pain results from pressure over the spinous apophyses of the first few cervical vertebræ or at the level of the upper pharyngeal region, or there is a revelation of soft gummatous areas; these lesions are undergoing evolution in a subject with a satisfactory general condition and who responds to a specific therapy. A positive Wassermann will naturally plead in favor of a specific lesion.

An important sign of the suboccipital localization of syphilis is revealed by the patient when he supports the head in his hands. We do not desire to give the impression that this is pathognomonic of caries of the upper cervical vertebræ, as has been put forth by some, because it does not appear to us impossible that a severe rhachidial pain, whatever its source, may not oblige the patient to consider the weight and mobility of his head as a cause of an increase of pain. Radiography is of immense value for the discovery of the lesion and too often is not resorted to, while a positive Wassermann is important.

The differential diagnosis must include traumatic lesions, chronic and gonococcic rheumatism, spondylosis, and above all, Pott's disease. Gonorrheal rheumatism has a sudden onset, while it has not the progressive element observed in syphilitic osteitis. In the former affection there is usually a more marked rise in temperature, while pressure over the cervical vertebræ does not reveal any localized pain.

Most important of all, however, is the differential diagnosis between cervical Pott's disease and syphilitic osteitis. In the former lesion the tuberculous syndrome, if we allow the expression, is quite different from the syphilitic syndrome. It is to be recalled, however, that hereditary syphilis often becomes an associate of tuberculosis, and as Ricord used to say, we have frequently to deal with a "scrofulate of pox," a combination distinctly influenced by specific treatment. This reserve being made, tuberculous heredity is generally devoid of syphilitic infection in the antecedents of the patient. For that matter, in his actual state, the tuberculous patient is to be separated from the syphilitic. Now, the latter is an adult, usually in a fairly good state of health, while the former is a child, frequently with a weak constitution and offering evidences of a bad general condition. The one offers the stigmata of specific taint, the other pulmonary or lymphatic tuberculous involvement.

Spontaneously painful, particularly at night or when the subject is at rest when the case is luetic, the lesion when tuberculous in nature gives rise to pain only on manipulation of the parts. Bacillary lesions give rise to abscess with elimination of few but large sequestra, accompanied by obstinate discharge. On the contrary, gummata give issue to a serosanguineous discharge or to a small quantity of thick pus and cause only infrequent, rapidly healing abscesses with multiple, small sequestra. The former are ameliorated by rest, while specific treatment improves or cures the latter, but never aggravates them.

The microscope will reveal the tubercle bacillus or Spirochæta pallida according to the case, while a positive Wassermann is a great help in detecting the luetic nature of the process, but is of less value when negative. It must be recalled that in some instances both clinical and laboratory data will be in default and then the diagnosis will be more or less difficult.

A NEW LIGHT IN MEDICINE.

The tendency of modern medicine is to progress away from internal medication. Witness the gradual diminution of the Pharmacopœia, the vogue of the psychanalysts, the popularity of nature cures, radium and the x ray, and the marvelous growth of surgery. The influence of sunshine on tuberculosis, the action of the x rays on malignant growths, and the beneficial effects which hydrotherapy has in certain nervous disorders, are all instances of the replacement of such drugs as creosote, arsenic, and the bromides by external therapeutics. In line with this movement is the discovery of a new form of light by an English investigator and called after him the Simpson light. This light is obtained from an electric arc formed between electrodes made by a special process from a mixture of the ores of several metals, the chief one being a tungstate of iron and manganese, known as wolfram.

The chief claim on medical attention of this new light is that it is extremely rich in ultraviolet rays and also has rays of shorter wave lengths, meaning obviously different physiological and therapeutic properties. Many experiments have been made at St. Bartholomew's Hospital, London, with the idea of deciding in just which particular field of medicine the Simpson light will find its greatest usefulness. It is still too early to generalize, but several interesting discoveries have been made. It seems to stimulate the healing of wounds; shrapnel wounds have been greatly benefited by the treatment. Cases of rheumatoid arthritis and of malignant growth have been treated with little or no appreciable result. Rodent ulcers have been healed by this light. It is believed, however, that its principal indications will

be found in certain diseases of the nose and throat, especially lupus and syphilis.

Like other similar methods, this treatment is not without its dangers. An erythema is often produced and the eyes must be protected or a conjunctivitis will follow. The necessary exposures are very short which is an added advantage in that a great number of cases can be treated in a short time. So far at least, this light seems to be a notable addition to the field of phototherapy.

THE DIGESTIBILITY OF EGG WHITE.

Common sense should dictate the dietetic use of egg white. Raw egg white, like milk, is an excellent culture medium for bacteria, and like milk suffers immediate bacterial contamination if exposed to the air at ordinary temperatures. Eggs should be chilled when newly laid, for egg shells are porous and do not prevent infection of the egg content; therefore raw egg white from eggs which have not received immediate refrigeration may well cause diarrhea. Cooked egg white, when exposed to boiling temperature (212° F.) or to the action of acids, becomes leathery in consistence and difficult of digestion; sterile egg white exposed to a temperature below 180° F. becomes jellylike, and by most individuals is as easily digested as raw sterile egg white, which itself is innocuous. A suggestive and analytical comment on the digestibility of egg white (Bateman, *Jour. Biological Chemistry*, August, 1916) appears in the department of Dietetics, Alimentation, and Metabolism in this issue of the Journal. It illustrates, however, a common tendency of research students to ignore the obviously matter of fact in favor of the recondite.

NASCENT IODINE TREATMENT OF TUBERCULOSIS.

Mr. Edward Bigg, of Bristol, writes to the *British Medical Journal* for August 19th, giving an account of a device, original with him, to administer nascent iodine. It almost completely prevents the fumes of chlorine gas from escaping and causing certain symptoms of poisoning.

Take a forty ounce stoppered bottle and charge with thirty-six ounces cold water. Prepare a smaller bottle (two to four ounce capacity) with a neck of the same diameter as that of the forty ounce; choose a sound wine cork which will fit both snugly, perforate for a glass tube, and cut a tube of such a length that, when connected, it will reach to the bottom of the forty ounce and half the depth of the smaller bottle. See that the fitting is correct, and that the two bottles can be connected easily and firmly. Then charge the smaller bottle with one and a half dram of powdered potassium chlorate; add three drams of pure hydrochloric acid, and rapidly and carefully insert the short limb of the tube, avoiding the entrance of the effervescing mixture into the tube by sloping the apparatus and inverting it. Then plug the cork into the forty ounce bottle, when gas will at once bubble up through the water. Leave the apparatus for three or more hours, when the reaction will be complete. Wash the residuum from the smaller bottle in the open air (or it may be added to the contents of the forty ounce if it is desired to use the potassium chloride which remains). No air release is needed.

News Items

Personal.—Dr. D. J. McCarthy, of Philadelphia, has returned home, after spending six months in Europe, during which time he made a survey of prison camps for the United States Government.

Hospital for Deformities and Joint Diseases.—A regular clinical meeting will be held in the dispensary building, 41 to 43 East 123d Street, New York, Tuesday evening, September 12th, at 8:30 o'clock. The paper of the evening will be read by Dr. Herman C. Frauenthal on Electricity in the Treatment of Infantile Paralysis.

American Electrotherapeutic Association. — The twenty-sixth annual meeting of this association will be held in New York, September 12th, 13th, and 14th, with headquarters at the Hotel Martinique. An excellent program has been arranged which includes the reading and discussion of thirty-five papers on the therapeutic use of electricity. There will be three scientific sessions, with a manufacturers' exhibition of electrical apparatus at 12:30 o'clock. Dr. Jefferson D. Gibson, of Denver, is president of the association, Dr. Byron S. Price, of New York, is secretary, and Dr. Frederick M. Law, of New York, registrar.

Dangers in the Manufacture of Explosives.—To safeguard employees connected with certain chemical industries, the American Public Health Association has taken the matter under investigation. At the coming meeting of the American Chemical Society, to be held in New York, September 25th to 30th, Dr. Alice Hamilton, chairman of the committee on Industrial Hygiene of the American Public Health Association, will present the matter in a comprehensive manner. Doctor Hamilton's paper will form a part of the program of the symposium on occupational diseases which has been arranged by the American Chemical Society.

Gifts and Bequests to Hospitals.—Mr. and Mrs. Harry Payne Whitney have contributed $10,000 toward the new children's and maternity ward to be added to the Newport, R. I., Hospital.

Contributions amounting to $27,500 have been received by the Volunteer Hospital, of New York, toward the construction of three additional stories, which the directors of the institution consider necessary.

Johns Hopkins Hospital, Baltimore, has received a collection of portraits of medical men valued at $100,000. The gift was made by Dr. Howard Kelly, a member of the staff of the institution, and Mr. Blanchard Randall, one of its trustees. The collection gives to Johns Hopkins Hospital one of the finest portrait galleries in the world.

Dental Schools Consolidate.—The New York School of Dental Hygiene has become allied with the Columbia School of Dentistry, and hereafter will be affiliated with the College of Physicians and Surgeons. The school will open on September 27th in the Vanderbilt Dental Clinic. A gift of $2,500 has been received from the Rockefeller General Education Board for the School of Dental Hygiene and the Columbia School of Dentistry has raised more than half of the $30,000 needed for temporary housing. The administrative boards of the two schools are practically identical: Dr. Louise C. Ball is dean of the School of Dental Hygiene, Dr. William J. Gies, treasurer, and Dr. Julia L. Mitchell, executive assistant. The executive committee consists of Dr. Louise C. Ball, Dr. William J. Gies, Dr. Edward F. Brown, Dr. Henry S. Dunning, Dr. Arthur H. Merritt, Dr. M. L. Rhein, and Dr. Louisa M. Webster.

Erysipelas and Workmen's Compensation.—The Connecticut Supreme Court of Errors has decided that a widow is entitled to compensation under the Connecticut workmen's compensation law for the death of her husband which resulted from erysipelas that developed after frostbite. He was an insurance solicitor and his duties required him to endure exposure to severe cold, which the compensation commissioner decided was the "proximate cause" of his injury. The main points in the opinion are published in the August 25th issue of *Public Health Reports.*

Clinical Congress of Surgeons.—The seventh annual session of the Clinical Congress of Surgeons of North America will be held in Philadelphia, October 23d to 28th, under the presidency of Dr. Charles H. Mayo, of Rochester, Minn. A tentative schedule of clinics and demonstrations to be given at this congress has been issued, which will be amplified and corrected so that the final program will properly represent the clinical work of Philadelphia surgeons. The committee on arrangements is planning for a complete showing of Philadelphia's clinical facilities in every department of surgery. Headquarters will be established at the Bellevue-Stratford Hotel. Dr. Franklin H. Martin, 30 North Michigan Avenue, Chicago, is secretary general of the congress; he urges surgeons who wish to attend the meeting to make application immediately for registration, as it is apparent that the limit of attendance will be reached weeks in advance of the date of the meeting.

Three Hundred Million Red Cross Seals to Be Distributed.—Three hundred million Red Cross Christmas Seals are being printed in Cincinnati for the annual holiday campaign to be conducted under the joint auspices of the American Red Cross Society and the National Association for the Study and Prevention of Tuberculosis. The campaign for the sale of Red Cross Seals this year will be larger than ever before. Although in 1915 the sale reached the record total of 80,000,000 seals, bringing in $800,000, it is expected that this year at least 100,000,000 seals or $1,000,000 worth will be sold. The sale will be organized from Alaska to the Canal Zone and from Hawaii to Porto Rico. Every State and Territory in the United States will have seals on sale. New organizations will be working in a number of the Western States, including Montana, Utah, and Wyoming. Distribution of the seals is now under way. The State Charities Aid Association, which has again been appointed agent for the sale of seals in New York State outside of greater New York, has already placed an order for 35,000,000 seals and hopes that its record of 10,464,092 last year will reach the 12,000,000 mark in 1916. In anticipation of increased sales, New York, together with other States has begun to organize the campaign considerably earlier than in former years.

Rockefeller Foundation Appropriations.—It is interesting to note that appropriations amounting to over $3,000,000 have been made by the Rockefeller Foundation this year. These appropriations, as announced in the official organ of the foundation for August 1st, are as follows: Previously reported, January 1 to June 30, 1916, $2,863,377.97; June 28, 1916, to the Rockefeller Institute for Medical Research for its current expenses, $80,000; June 28, 1916, to the Rockefeller Institute for Medical Research for the cost of alterations in the laboratory and hospital buildings, $80,303.72; July 11, 1916, to the American Red Cross for relief in Serbia, $15,000; July 11, 1916, to the International Committee of Young Men's Christian Associations for the establishment and maintenance of recreation centres in connection with the military forces on the Mexican border, $50,000; July 14, 1916, for the assistance of the Department of Health of the City of New York in controlling the epidemic of infantile paralysis, $50,000; July 18, 1916, to the American Social Hygiene Association for its current expenses, $7,000; July 18, 1916, for the protection, maintenance, and education of Belgian children in Switzerland under the direction of the War Relief Commission, $25,000; July 31, 1916, to cover appropriations, China Medical Board, $198,985.78; total, January 1 to July 31, 1916, $3,369,667.47.

Death Rate in New York.—During the week ending September 2, 1916, 152 deaths were reported as due to infantile paralysis, compared with 209 during the previous week and 301 for the week ending August 12th. It is encouraging also to note that the mortality of the contagious and diarrheal diseases continues to remain lower than during last year. The mortality of the following diseases was lower during the past week than during the corresponding week of last year: Measles, whooping cough, typhoid fever, cerebrospinal meningitis, diarrheal diseases, pulmonary tuberculosis, and diseases of the nervous system.

The total number of deaths reported during the week was 1,388 compared with 1,515 reported during the previous week, the death rate for the past week being 12.96, compared with 14.13 for the week ending August 26th. The death rate for the first thirty-six weeks of 1916 was 14.51 and the death rate for the corresponding period of last year 14.42.

American Association for the Study and Prevention of Infant Mortality.—The seventh annual meeting of this association will be held in Milwaukee, October 19th, 20th, and 21st, with headquarters at the Hotel Wisconsin. The subjects to be discussed include: Governmental activities in relation to infant welfare; care available for mothers and babies in rural communities. standards for infant welfare nursing; morbidity and mortality in infancy from measles and pertussis; public school education for the prevention of infant mortality; vital and social statistics. Dr. S. McC. Hamill, of Philadelphia, is president of the association, and Dr. William C. Woodward, of Washington, president-elect for 1917. Dr. George C. Ruhland, Health Commissioner of Milwaukee, is chairman of the committee on local arrangements. Special sessions are announced which will be devoted to obstetrics, pediatrics, governmental activities, and vital and social statistics propaganda, public school education for the prevention of infant mortality, rural communities and nursing and social work. The session on pediatrics will be a joint one with the Milwaukee County Medical Society. The session on governmental activities will be a joint one with the committee on vital and social statistics, and the session on rural communities will be a joint one with the committee on nursing and social work. Programs or other information in regard to the meeting can be secured from the Executive Secretary, 1211 Cathedral Street, Baltimore, Md.

Civil Service Examinations.—Among the positions for which the Civil Service Commission of the State of New York will hold examinations on September 30th are the following:

Assistant physician, regular or homeopathic. This examination is intended to provide eligibles for the position of assistant physician in the State hospitals and for other positions of a similar nature in various State and county institutions. Salary in the State hospitals $1,200, increasing $100 each year to $1,600, with maintenance, including quarters, board, laundry, etc. Examination open to men and women who are licensed medical practitioners in this State, who have graduated from a registered medical school and who since graduation have had one year's experience on the resident medical staff of a general hospital, or as medical intern or clinical assistant in a State hospital or institution or have been engaged for three consecutive years in the practice of medicine. Open to nonresidents; unmarried men preferred.

Woman physician (regular or homeopathic), State hospitals and institutions. $1,000 to $1,500 and maintenance. Candidates must be licensed medical practitioners of the State of New York, and must have had at least one year's experience on the medical staff of a hospital or three years' experience in the general practice of medicine. Open to nonresidents.

Laboratory assistant in bacteriology, State Department of Health. Men and women, $720 to $1,200 a year. Open to nonresidents and noncitizens. Only candidates who have satisfactorily completed a systematic course in bacteriology and have also had not less than eight months' practical experience in laboratory work will be accepted.

THE PROPHYLACTIC USE OF ANTITETANIC SERUM.

By W. H. Luckett, M. D.,
New York,
And Roberts S. Knapp, M. D.,
New York.

The serum treatment of surgical conditions, in our experience, has in most instances been very discouraging, in fact more or less useless, particularly in conditions where it seemed to be most needed; for instance, in the more virulent type of infections and where the patient seemed to be unable by himself to take care of the infection. There is, however, a most noteworthy exception. The present war in Europe, with the reports that reach us particularly from northeast France and the Austro-Russian and Serbian fronts of the numerous cases of tetanus following gunshot wounds, reminds us of the advisability of recording and calling attention to our work here with the hope that the preventive use of antitetanic serum may become a more routine treatment for all suspicious wounds.

In estimating the efficiency of serum therapy in general, the fact must always be taken into serious consideration that in by far the majority of cases the body itself seems to be perfectly able to take care of the infection. How much this is true of tetanus is most difficult of demonstration.

Ten to fifteen years ago one of us used regularly to report cured cases of tetanus from wards of the Harlem Hospital and in private. For the past ten years since we advocated and practised the preventive use of the antitetanic serum injection, we have not had develop in the wards of the Harlem Hospital a single case of tetanus on our service.

The difficulty of isolating the tetanus bacillus from an infected wound; the fact that positive clinical tetanus is frequently encountered in which the bacillus, after most thorough bacteriological search, could not be found; and the urgent necessity of making a prompt injection; long ago determined us to use the antitetanic serum as a preventive in all puncture wounds, gunshot wounds, compound fractures where the bone had probably become infected by coming in contact with the street soil, and in fact in all suspicious dirt contaminated wounds, particularly of the hands and feet, without wasting time in waiting for the bacteriological report, for time is a most important factor.

The following figures are taken from the records of the Harlem Hospital for the past ten years ending January 1, 1916, and show that during that decade antitetanic serum was administered as a prophylactic dose as follows:

In compound fractures	696	cases
In gunshot wounds	595	"
In stab wounds	337	"
In punctured wounds (mostly of hands and feet)	575	"
In suspicious dirt contaminated cases of lacerations, cellulitis and burns of various parts of the body	46	"

making a total of 2,239 cases, not one of which exhibited any of the signs or clinical manifestations of tetanus. We have yet to note harm, danger, or complications from its administration. Before we regularly employed as a routine the preventive injection, this class of cases gave us annually four to six cases of tetanus.

Technic of administration. Wash skin at site of injection with ether and alcohol, paint surface with tincture of iodine three per cent., give 1,500 units of antitetanic serum intramuscularly or subcutaneously, preferably the former, massage over point of injection, paint needle wound with tincture of iodine, cover with small "collodion butterfly"; if wound is near a large nerve trunk inject serum directly into wound or as near nerve as possible.

The so called delayed tetanus may manifest itself a month or two after the original wound. It is a very serious condition and may demand more than one preventive dose, especially if the wound continues to suppurate, in which case a preventive injection every seventh or eighth day is indicated. If in the course of repair of such wounds an operation becomes imperative, another injection is indicated.

We purposely do not mention the local treatment of the wound, as it is today about the same as it was when we were seeing so many cases of tetanus, and this impels us to give credit to the antitetanic serum.

THE TREATMENT OF SPRAINED ANKLE.

By S. Bernard Rosenzweig, M. D.
New York.

The first step in the treatment of sprains of the ankle should be a careful radiographic examination made by a competent röntgenologist. Within the last few years, routine x rays have demonstrated the comparative rarity of simple sprains compared with oblique fractures of the malleoli without displacement, and transverse fractures just above the joint margin. The differentiation is essential because the treatment differs.

In the simple sprain, mobilization and massage are indicated. Painful at first, continuation of the treatment brings early relief. The ankle is soaked for fifteen to twenty minutes in water as hot as the patient can bear. This is followed by massage and passive movements, after which alternating hot and cold douches are given, and a large, loose evaporating dressing of lead and opium wash is applied. This is carried out twice daily, and after seventy-two hours the patient is induced to move his ankle himself. Thereafter, the swelling having subsided, the ankle is strapped for support and the patient advised to walk about. A cane may be necessary at first, but should be discarded early. At the end of ten to fourteen days, the patient is able to be around with practically no discomfort. A high laced shoe should be worn for some time to support the joint; leather anklets are generally inefficient and uncomfortable. Whenever the facilities permit, the pa-

tient should be given daily bakings from the beginning. The absorption of the exudate is enhanced and painful sequelæ are avoided.

When the actual condition is a "sprain fracture," immobilization by means of a heavy adhesive dressing or a light plaster splint of a removable type is indicated. Massage, baking, and mobilization are given at the end of a week, after which the patient is permitted to bear weight on the limb, the support being continued for another fortnight or so, depending on the extent of the injury. Aftereffects, such as weak arch and contracted heel cord, are prevented by maintaining the foot in marked dorsiflexion and inversion while it is kept immobile. Here, as in simple sprain, early motion and use are important.

Some Unusual Uses of Rubber in Surgery.—Saint-Martin, at a recent meeting of the Société de chirurgie (*Presse médicale,* July 13, 1916) reported that, in cases of nerve injury, pieces of rubber tubing were passed around nerves freed at operation from compression by fibrous or other tissues, in order to keep these nerves isolated from surrounding structures. The radial or ulnar nerves were involved. The rubber was still being perfectly borne from two to four months after operation. In another case, a small rubber ball shaped like a human testicle was substituted for an injured testicle without the patient's knowledge. The rubber substitute was borne perfectly, and the patient remained free of concern about his injury.

Typhus Fever.—F. Meyer, A. Klink, and E. Schlesies (*Berlin. klin. Woch.,* February 21, 1916) advise general treatment, including chiefly open air living, and measures to protect the heart. From the first, small doses of digitalis should be given, so that during the critical period the heart will be under the full influence of the drug. Later large doses of caffeine and camphor should also be given; during the unconscious stage saline and glucose infusions are required. General nursing should be scrupulously attended to, and cold baths or cold packs should be used to reduce the severity of the nervous symptoms. Neither salvarsan nor convalescent serum has yielded good results, but on the theory that the disease might be of protozoal origin optochin was tried in forty-six cases in oral doses of 0.25 gram six to ten times daily, until the temperature fell nearly to normal. In some very severe cases 0.25 gram was given intravenously once a day, or two or three intramuscular injections per diem of 0.25 to 0.5 gram dissolved in camphor oil with the aid of alcohol. Toxic symptoms other than the most trivial were not present, but when complaint was made of visual disturbance, the drug was reduced in amount. No decided effect on the fever was produced, but optochin caused a marked subjective improvement and a general reduction in the severity of the disease, particularly in nervous symptoms. It did not seem to have any influence in preventing injury to the heart or late gangrene and thrombosis. Quinine was found to have the same action as optochin, but was much less effective.

Extirpation of the Lacrymal Sac Without Scar.—J. A. Kearney (*Medical Record,* August 19, 1916) describes his method of removal of the tear sac by way of the slit canaliculus. It is best done under ether anesthesia, and its advantages are absence of scar on the face, less difficulty therefore in obtaining the consent of the patient to operation, and great lessening of hemorrhage during the operation. A return of the condition is impossible because the mucous lining is ablated from the puncta to the upper portion of the nasal duct. There is immediate cessation of sac secretion after this operation, with a gradual disappearance of epiphora.

Gillet Operation for Intestinal Stasis.—A. J. Ochsner (*Illinois Medical Journal,* August, 1916) describes this operation which gives greater promise than others. In consists in severing the ileum at the most convenient point to make an anastomosis with the lower end of the sigmoid flexure of the colon. After the anastomosis, the upper segment of the sigmoid is passed through a buttonhole in the anterior abdominal wall on the left side. The distal end of the ileum is closed and is dropped back into the abdominal cavity. The colon is not disturbed by the operation, and what little mucus gathers in the colon can be washed away by an enema given once a week through the colostomy opening.

Pregnancy in the Tuberculous and Its Management.—C. C. Norris (*American Journal of Obstetrics,* June, 1916) reports sixty-eight cases, and asserts that, except in the advanced cases of pregnancy, coexisting tuberculosis has little or no tendency to produce abortion, miscarriage, or premature labor. In about twenty per cent. of mild, quiescent cases, however, and in seventy per cent. of more advanced cases, exacerbations of the tuberculous process occur during pregnancy or the puerperium. Pregnancy should be avoided by tuberculous women unless the disorder is in the first stage and has been quiescent for at least two years. If, before the fifth month of pregnancy, evidences of activity of the disease appear, the uterus should be emptied, preferably by curettage during the first six or eight weeks and in later cases by vaginal hysterotomy. When pregnancy is thus interrupted, the prognosis is greatly improved, though amelioration of the lung condition is not positively insured. Before the fifth month of pregnancy, evacuation of the uterus, as soon as acute symptoms arise, leads to definite improvement in sixty-five to seventy per cent. of cases, provided suitable aftertreatment is applied. Intervention postponed a week or more from the onset of the exacerbation yields less satisfactory results. After the fifth month of pregnancy, expectant treatment is generally best. Labor should be made as easy as possible, the patient being rarely, if ever, allowed to go to term, but delivered by induction of premature labor two weeks before term. At labor, forceps or version is usually indicated. Throughout, hygienic and dietetic treatment should be applied; the patient should be carefully examined at regular and frequent intervals. Tuberculous mothers should not be allowed to nurse their infants, which should be especially guarded from infection.

Management of Empyema in Childhood.—A. Merrill Miller (*Illinois Medical Journal,* August, 1916) insists that aspiration is only an emergency procedure and that rib resection is the cure. To keep the opening patent and encourage free draining he prefers the self retaining rubber spool, which has the advantage of presenting a flat surface for the application of dressings. Anesthesia must be light to preserve the coughing reflex. Sunshine and fresh air are of the utmost importance in after-treatment.

Economic Use of Costly Alkaloids.—N. Bishop Harman (*Brit. Med. Jour.,* August 5, 1916) states that for ophthalmic practice solutions of several expensive alkaloids must be kept continually on hand, but they tend to deteriorate, grow moulds, and become contaminated with various bacteria so that there is much waste. These disadvantages can be entirely overcome by the use of the following solvent:

Tincture of iodine, ...0.03;
Methyl salicylate, ...0.25;
Distilled water, ...500.00.

This should be well shaken, put into a stoppered bottle, and is ready for use after twenty-four hours. It will keep sterile indefinitely even when opened frequently. It is slightly irritant, increasing the initial burning of an instillation to a trivial degree. Viscid solutions are preferable to thin ones and they may be prepared either by dissolving the alkaloidal base in castor oil, or by the use of the alkaloidal salts dissolved in the foregoing solvent to which acacia has been added in amount about eight times that used in the mucilage of acacia, that is, about five grams per mil of the solvent. Viscid solutions are more economical than thin ones, and spread more uniformly over the entire conjunctival sac.

Benzol in the Treatment of Leucemia.—Joseph M. Barry and Jane M. Ketcham (*Journal of the Indiana State Medical Association,* August 15th) report the case of a woman twenty-nine years of age with leucemia, who was admitted to the hospital July 28, 1914. She was kept in bed, placed on a forced diet, and benzol treatment was instituted. Five mm. of benzol were given three times a day, and the dose was gradually increased until the maximum quantity given was thirty-five mm. three times a day on October 7th. It was given at first in an emulsion with olive oil, but later was administered in capsules after meals. The patient complained sometimes of eructations, but at no time did any vomiting or nausea occur. She sat up in a wheel chair for the first time on September 28th, and the benzol was discontinued on October 28th. She had gained twenty-seven pounds in weight and the spleen was no longer palpable. After discontinuing the benzol, iron, quinine, and strychnine were given by mouth, and one and a half grain of citrate of iron hypodermically twice a week. In the discussion of this paper C. S. Bond urged that care must be exercised in the use of benzol not to have it produce too great an effect, and that it would be well to stop the drug when the leucocyte count is slightly less than 40,000 or 50,000, and then see what follows, but if it is discontinued too soon we are liable not to get the desired result.

Value of Vaccines in Gonorrhea.—G. Cappelli (*Giornale italiano delle malattie veneree e delle pelle,* June 12, 1916) states that vaccine administration alone is insufficient to control or cure the conditions in the original sites of infection, such as the urethra, vagina, and conjunctiva, but is of help in what may be called secondary localizations of the gonococci, such as epididymitis and arthritis. Vaccines are more or less uncertain in points which have a direct communication with the urethral canal, such as Cowperitis and prostatitis. The reason for this is not clear, although it may be that the immune bodies can better restrain the growth of the gonococci when allowed to act upon them in a closed or isolated place.

Treatment of Epidemic Poliomyelitis.—Herman B. Sheffield (*Medical Record,* August 19, 1916) reports the results of his treatment in thirty-three patients of whom nine died, including six within forty-eight hours of the onset. The treatment consisted of the application of six to ten cups on each side of the spinal column, hot mustard baths at a temperature of 101° to 105° F., every six hours, one or two grains of ammonium salicylate for each year of the child's age every two to six hours, with small doses of strychnine. Lumbar puncture was done where there was pronounced rigidity or twitching, with the hypodermic use of camphorated oil in case of respiratory difficulty. Immobilization of the paralyzed limbs, light massage and passive movements were used at once even in the acute stages.

A New Antiseptic Fluid for the Treatment of Wounds.—P. Duret (*Bulletin de l'Académie de médecine,* July 11, 1916) recommends the following preparation, which is not only germicidal, but is an active stimulant to phagocytosis, and keeps the tissues under the best conditions for combating microbic invasion:

℞ Calcis chlorinatæ, ...28 grams;
Magnesii sulphatis, ...18.2 grams;
Aquæ, ...1,000 grams.
Fiat solutio.

The two salts are triturated in a mortar, then gradually dissolved in the water, and the solution filtered through cotton in a funnel. A clear solution is thus obtained which contains magnesium hypochlorite, chloride, hydrocarbonate, hydrate, and oxychlorides. It is isotonic with the blood serum, is alkaline to litmus, yields its own volume of gaseous chlorine, and is more stable than Labarraque's solution (liquor sodæ chlorinatæ) or Dakin's solution, losing less than half its chlorine when left twenty days in an open bottle in the light and at room temperature. In wounds it gives off its chlorine slowly, and as it decomposes yields magnesium chloride and hydrate which form soluble oxychlorides and double oxychlorides of magnesium and sodium. After mechanical cleansing and removal of foreign bodies from a wound, the latter should be copiously irrigated with the solution at 35° C. To secure rapidly a strong antiseptic action from it, hydrogen dioxide solution, diluted one in ten, may be brought in contact with it over the tissues, thus accelerating the liberation of chlorine. Finally, the froth may be driven out of the wound with the magnesium solution alone, in which the wound is then bathed.

Treatment of Scabies by Sulphur Dioxide.—John Bruce and Stanley Hodgson (*Brit. Med. Jour.*, August 5, 1916) report that as the usual treatment of scabies by sulphur ointment requires from one to two weeks, experiments were undertaken to devise a more rapid method, and the use of sulphur dioxide was adopted as the most satisfactory. The patient is first given a hot bath, in which he allowed to soak for five minutes; he is then rubbed well with soap and the skin scrubbed to open the burrows. He is then enclosed in a tight chamber, constructed on the plan of a home Turkish bath cabinet, in which he sits on three narrow bars. His head is outside of the chamber and about his neck a moist towel is wrapped closely to prevent the escape of the fumes. He has fifty minutes' exposure to sulphur dioxide fumes from a large, slow burning sulphur candle, and then is dressed in clean warm clothing. All of his clothes previously worn must be sterilized by similar fumigation or by steam. One treatment cures ninety-eight per cent. of cases and gives immediate relief from itching. The treatment at times causes temporary erythema.

Autotherapy.—Charles H. Duncan (*Long Island Med. Jour.*, August, 1916) points out that all experience shows that the body contains within itself the natural agents for the cure of disease. Upon this basis the author has elaborated a system of drugless therapy in which he seeks to utilize and enhance the normal curative agents. Thus in localized purulent infections cure can be assured promptly by the administration of a few drops of the pus orally in some water. In other infections—chiefly the systemic ones or those in which the pus pocket is not accessible—cure will result from the subcutaneous injection of small doses of the patient's own blood diluted with physiological salt solution. Similarly, autotherapy is practised successfully in the employment of measures to provoke hyperemia, such as Bier's methods, local applications of heat, radiation with x rays, radium and ultraviolet rays, and the use of diathermy. A further elaboration of the method consists in the injection of the bacteria-free filtrates of pathological exudates. The cure of syphilis by injection of distilled water, as recently reported, is another illustration of the same form of treatment.

New Method of Bloodless Circumcision.—Henry Curtis (*Practitioner*, August, 1916) grasps the prepuce on each side of the median dorsal line with two pairs of forceps, the points of which are pushed up to the level of the corona glandis. The prepuce is then divided with scissors along the median line between the forceps into two lateral flaps, each of which is carefully separated from the glans as far as the groove behind the corona, so as to evacuate inspissated smegma, and then is clamped from below upward, at a distance of about a sixth of an inch from its attachment in the circumcoronal region. The clamp, in the case of each flap, is applied with the point directed upward and inward, i. e., toward the median dorsal line, the angle of union of the blades being made to lie at a point about a sixth of an inch distant from the frænum. Generally a third clamp is needed in order to secure bloodlessness. It is essential to apply this clamp so that there is no interval of prepuce left unclamped between the first and second clamps from which oozing could occur. A catgut suture with a short straight needle at each end is then introduced in each lateral flap in the following way: Beginning near the free lower edge, about an eighth of an inch from it, and at the same distance from the frenum, one needle is passed from mucous membrane to the skin just proximal to the clamp, the catgut pulled half way through, and the second needle passed through the same stitch hole in the opposite direction, and the suture drawn taut. Other similar stitches are made until the cut edge of the flap is reached, when the ends of the suture are tied. The clamps are then removed and the redundant prepuce is trimmed off just distal to the suture.

Practical Aspects of the Ovarian Secretions.—William P. Graves (*N. Y. State Jour. Med.*, August, 1916) reports that in ovarian therapy much better results are to be obtained by the use of extracts of the whole ovary than of those made from the corpus luteum alone. In addition to their lesser efficiency, the luteum extracts are prone to disturb the digestion, while ovarian extract is seldom toxic. The ovarian extracts give excellent results in genital hypoplasia, atrophy, after removal of the uterus and ovaries, and in the menopause. They are also helpful in the amenorrheas and in many other forms of menstrual disturbance, including irregularities and dysmenorrhea. Even certain cases of sterility have been benefited by the use of ovarian extract.

Immobility after Joint Injury.—John Collie (*Lancet*, August 5, 1916) states that if proper methods of treatment and aftercare are instituted, the occurrence of immobility following injuries to or about the joints can be largely obviated. The practice of prolonged immobilization is responsible for most of the stiffness, through formation of adhesions within the joint and thickenings and adhesions in the tissues about the joint, including the tendon sheaths. Where such immobility has occurred it may largely be overcome by proper measures. In either case, the essential features of treatment are maintenance of mobility through massage and passive or active movements. Where adhesions have already developed they should be broken down under a general anesthetic which abolishes muscular spasm. Then within twenty-four hours at most, movements must be begun gradually and without producing more than slight pain, in order to prevent reforming of the bands. Massage and electrotherapy should be used wherever a limb has to be immobilized, in order to maintain the nutrition and functional capacity of the muscles. Following a period of passive movement, the patient should be encouraged by every possible means to perform active movements to develop the weakened muscles, but these movements are often somewhat painful and must be carefully guided so as to minimize pain. Attention should also be given to prescribing specific forms of exercise to make sure that the affected muscles are actually being trained.

Deep Röntgen Therapy in Chronic Progressive Pulmonary Tuberculosis.—Bacmeister (*Berlin. klin. Woch.*, Feb. 14, 1916) states that clinical experience has confirmed the experimental work of Bacmeister and Küpferle regarding the curative value of deep irradiation in chronic tuberculosis. The treatment is in no sense specific, for the tubercle bacilli are not destroyed. Its value lies in stimulating cicatrization of the tuberculous granulation tissue. Three or four applications per week of fifteen erythema doses, combined with the application of the quartz lamp rays, usually lead to prompt healing of chronic, progressive pulmonary tuberculosis, even in cases with fever and sputum containing elastic tissue and tubercle bacilli.

Treatment of Anterior Poliomyelitis.—Charlton Wallace (*N. Y. State Jour. Med.*, August, 1916) states that preventive measures similar to those taken in diphtheria or scarlet fever should be carried out and the first stage of the disease should be treated by laxatives and the administration of hexamethylenamine or salol. Heat applied to the spine and tender muscles is efficacious in the relief of pain, and the patient should be kept at absolute rest on a firm fracture bed. Plaster of Paris bandages should be applied to the feet to prevent contraction of the tendo Achillis. During the stage of apparent paralysis the patient should be kept in bed, and plaster of Paris dressings or even complete casts should be kept on to prevent contractures and stretching of the weakened muscles. After this stage daily muscle massage and manipulation should be begun, and braces should be fitted to protect against severe strain of the weakened muscles. Electrotherapeutics should be a part of the first year's treatment. Functional use of the affected muscles, under protection of proper mechanical appliances, should be encouraged, but muscle education is contraindicated, since it is useless and even harmful. Various operative measures are of great value after determining their absolute need.

Local Anesthesia in Intrathoracic Surgery.—Couteaud and Bellot (*Bulletin de l'Académie de médecine*, July 18, 1916) have succeeded in extending the field of local anesthesia to intrathoracic interventions, in which general anesthesia had hitherto alone seemed applicable. The method was used especially for the extraction of projectiles imbedded in the lungs. A preliminary injection of morphine was always given. The local anesthetic solution used was a mixture of one part of a one in 200 solution of cocaine hydrochloride with two parts of a like solution of stovaine, a few drops of adrenaline solution being added. Occasionally a more dilute solution was employed or a one in 400 solution of stovaine used, thus replacing novocaine, which was unobtainable. Properly employed, these solutions can be carried freely and with impunity over the pleurocostal tissues, permitting necessary rib resections, entrance into the thorax, and deliberate manipulations of the lung, without fear from operative pneumothorax. By this means the removal of foreign bodies in about thirty cases was satisfactorily effected. These were cases of local intolerance of the foreign body, the wounds having been sustained some time before. In twenty instances the missiles extracted were in the lung, and in one instance in the apex of the left ventricle. In eight cases the lung opened into was largely, or completely free of adhesions, pneumothorax resulting and the missile being removed after fixation and delivery of the lung from the wound. Uniformly the lung was observed, after penetration through the properly anesthetized chest wall tissues, to be, unless inflamed, entirely free of sensation. The organ could be seized, pulled out, and manipulated without the least pain. The pneumothorax itself caused merely a quite bearable respiratory difficulty, followed by a stitch which rapidly passed off, frequently without causing any change in the patient's facies. Shock was practically nonexistent. The pneumothorax was established less suddenly and completely than in the generally anesthetized patient, complete collapse of the lung never taking place. The waking patient proved, in fact, of marked assistance to the operator himself, being able, by cough and voluntary respiratory activity or rest, and according to the surgeon's directions, to drive his lung toward the chest opening practically at will, thus limiting the extent of the pneumothorax and often rendering useless the subsequent aspiration of air from the pleural cavity. In one case a shell fragment imbedded at the hilum of the lung, nine cm. deep, was thus removed, the surgeon's hand palpating during the procedure the mediastinal organs, heart cavities, and pulsating aorta without a wince from the patient. All the cases operated in terminated favorably.

Treatment of Chronic Gonorrhea in the Female.—George A. Lassman (*Jour. Florida Med. Ass.*, July, 1916) has found that before beginning treatment we must make certain of the diagnosis, and if there is but little secretion a pure glycerin tampon should be inserted and allowed to remain for twelve to eighteen hours, when a copious secretion will have accumulated. The first requisite is to adopt measures for improving the patient's general health and to avoid all internal medication which may impair it. Since the infection is purely local, cubeb, sandal oil, copaiba, and methylene blue should not be given, since they tend to disturb digestion. The urethra and bladder should be irrigated with potassium permanganate solutions, beginning at about one in 10,000 and increasing to one in 800. The bladder should be filled with the solution by injection through the urethral orifice with the aid of an acorn tip nozzle. For the vagina, protargol in ten to twenty per cent. solution is the best, and it may well be combined with the insertion of glycerin, boroglycerin, or protargol-glycerin tampons, which should be retained for about ten hours at a time. Douches of permanganate of potassium, one to 3,000 to one to 300, should also be ordered and the patient should be directed to hold the labia closed about the nozzle to secure distention of the vagina. The cervix should be cauterized with pure phenol followed by alcohol, and using an acorn nozzle of soft rubber pressed firmly into the external os, the uterine cavity should be filled with a two per cent. solution of protargol. This treatment should be continued until repeated smears are negative for gonococci.

Miscellany from Home and Foreign Journals

Use of Trypsin in Broth for Blood Cultures.—S. R. Douglas and L. Colebrook (*Lancet*, July 29, 1916) from a series of bacteriological experiments, here recorded, reached the conclusion that the use of a broth containing trypsin gave much better results in blood cultures than were obtainable otherwise. This was true for all organisms tested, and not for a restricted few. The addition of trypsin to the broth overcame the antitryptic property of the blood, prevented clotting, and neutralized the antibacterial powers of the blood. The broth should contain five per cent. of trypsin solution and the blood culture should be made with one c. c. of blood in five c. c. of the broth.

The Pathogenicity of Lamblia intestinalis.—H. B. Fantham and Annie Porter (*Brit. Med. Jour.*, July 29, 1916) state that there has been much dispute as to the pathogenicity of this parasite (Giardia intestinalis), but the personal experience of the authors with 187 cases of pure lambliasis has convinced them that the parasite is pathogenic for man. The symptoms are weakness, stools of varying and peculiar colors—yellow, brown, putty colored, white, etc.—and of consistence varying from solid to diarrheal, with blood at times, and with concurrent lymphocytosis. The disease is not restricted to the tropics, but is found in temperate regions as well. Animal feeding experiments made with material from the stools of patients showed the parasite to be pathogenic for cats, mice and rats. Different strains varied widely in virulence. It is suggested that rodents may be the reservoirs of this parasite from which man derives his infection, and this seems to be supported by the considerable number of cases coming from the trenches in Flanders, where rodents are present in great numbers.

Municipal Control of Poliomyelitis.—Abraham Sophian (*Jour. A. M. A.*, August 26, 1916) remarks that evidence points strongly to the dissemination of poliomyelitis mainly through contact with the sick and by the medium of healthy human carriers. Other agencies of transmission have not been excluded, and some even have been shown to be possible factors in experimental infections. Such include flies, various insects and animals, dust, dirt, contaminated food, garbage and refuse. Since the nasopharynx harbors a virus resistant to drying, it follows that coughing, sneezing, and spitting can spread the disease. The virus is also present in the stools of infected persons; fecal matter, therefore, requires complete disinfection. Municipal control should take cognizance of all these facts and all cases should be treated in hospital to secure adequate quarantine, which should last eight weeks. All contacts should be quarantined under observation for ten days and ordered a spray of salt solution and one per cent. peroxide of hydrogen for the nose and throat. No contacts or children under ten years of age should be admitted to the community and every agency should be employed to clean up the city, prevent spitting, and to educate the general public in the means of prevention.

Effect of Surgical Procedures on Blood Sugar and Renal Permeability.—Epstein, Reiss, and Branower (*Journal Biological Chemistry*, August, 1916) point out that although the amount of sugar in the blood is invariably increased after operations, yet glycosuria after operation occurs only occasionally, one case in fifty showing traces of sugar. By careful examination of patients in whom no evidences of renal disease were present, they found that one of the effects of the surgical procedures was a diminution in the amount of urine. The authors conclude, therefore, that a reduction or an impairment of renal function is responsible for the infrequent elimination of sugar in the urine after operations.

Congenital Acquired Scleroderma in Childhood.—E. A. Cockayne (*British Journal of Children's Diseases*, August, 1916) points out the confusion which exists between this disease and sclerema neonatorum. As the result of the study of 100 cases he concludes that females are affected more often than males. In sclerema the sexes are equally affected. The commonest form of the disease in childhood is that with isolated plaques or bands of induration. Sclerosis of muscles may be a primary condition in scleroderma, another manifestation of the disease being myositis ossificans. As to the causative factor of scleroderma, little is known. According to one hypothesis it is a trophoneurosis due to disease of the sympathetic system.

Rational Diagnosis of Pulmonary Tuberculosis.—E. Rist (*Presse médicale*, July 13, 1916) deplores the frequent misuse of the procedures now available in the diagnosis of tuberculosis of the lungs, and likewise the tendency toward hastily labelling all cases of chronic cough, hemoptysis, fever, or loss of weight as tuberculous, and thereafter neglecting to apply diagnostic methods which will establish the diagnosis with certainty. It has been disproved of late that a stage of germination of the disease can last several months or years, during which the tuberculous lesion, detectable upon auscultation, has supposed to progress without expectoration of tubercle bacilli. Practically every adult individual is a case of healed tuberculosis, and active disease in the adult is merely the result of reinfection, a stage of germination in fact continuing throughout life. Active lesions nearly always occupy from the first an extensive portion of lung tissue and not infrequently a cavity is formed in their central portion within a few weeks. With few exceptions, the stage of germination is wanting or is brief. Yet attempts are still made to detect this stage, the physical signs of which have been formulated theoretically, on a mistaken pathological basis. A diagnosis of tuberculosis made by percussion and auscultation is useless from the standpoint of prophylaxis and cure. Great care, skill, and experience are, therefore, necessary in the earlier detection of the disease by these measures. Impaired breath sounds may be due to

atelectasis from bronchial obstruction instead of to induration of the lung; hence the absolute necessity of previously unblocking the bronchi by having the patient cough repeatedly, and controlling the bronchial timbre by the pectoriloquy test before reaching a definite conclusion. A much larger number of cases of central lesion are negative to auscultation and percussion than is generally supposed. X ray examination, which reveals such lesions, is therefore essential in a complete diagnostic inquiry; this reveals smaller diseased areas than do percussion and auscultation, and absolutely proves the lung to be normal when an experienced eye finds no shadow on the radiographic plate, thus preventing mistaken conclusions of disease based on the physical signs alone. Finally, examinations of the sputum for tubercle bacilli are also indispensable. Pulmonary affections in which repeated sputum examinations prove negative should be held nontuberculous, and these examinations should be made even in apparently certain cases of tuberculosis with cavity formation, lest one overlook instances of suppurative hydatid cysts, abscesses of the lung, open interlobar pleurisies, lung syphilis, bronchiectasis—all affections often yielding the same auscultatory signs as tuberculosis. By combining all the diagnostic procedures referred to, positive diagnoses may be made in a few days which would ordinarily remain in suspense for months, with corresponding delay in the intelligent application of treatment.

Spasmophilia.—J. P. Sedgwick (*Lancet-Clinic*, August 5, 1916) defines this condition as one of abnormal irritability of the nervous system, especially common in early childhood, and characterized by galvanic as well as mechanical hyperexcitability of the peripheral nerves and a tendency to tonic and chronic convulsions. At certain times of the year, over thirty per cent. of all infants show evidences of it. The criterion of spasmophilia is an anodal opening contraction with the Stinzing normal electrode over the peroneal nerve, behind the head of the fibula, with a current of less than five milliamperes. True laryngospasm, tetany in children, most of the convulsions of children, and spastic apnea have been shown to be but manifestations of an underlying spasmophilia. The Chvostek phenomenon, or muscular contraction about the mouth upon tapping the cheek over the facial nerve, is often present in spasmophilia, and the Trousseau phenomenon, or tetany position of the hand upon constriction of the arm, is pathognomonic. The condition is often familial, and Sedgwick has found heightened electric excitability in the nursing mothers of all spasmophilic infants less than one year of age. Many cases of frequently repeated mental absences in children, resembling petit mal, are due to spasmophilia, and are unrelated to epilepsy and hysteria. Such end in spontaneous recovery. The brains of spasmophilics show a low calcium content. The treatment is usually effective and, as hitherto recognized, consists in the withdrawal of cow's milk and substitution of breast milk, when possible, or of carbohydrates in the form of gruels, and the giving of codliver oil, phosphorus, and sedatives, such as chloral hydrate, when necessary in the active stages. Sedgwick, from his recent experience, strongly recommends calcium salts in these cases, as giving quicker and more definite results. He administers ten c. c. of a ten per cent. solution of calcium chloride, mixed with orange or other fruit juice and water, four or five times daily; frequently also a teaspoonful of a one in 10.000 solution of phosphorus in codliver oil morning and evening. In the acute and subacute cases in one year infants, brilliant results were obtained with calcium chloride, and in more chronic and very severe cases, as well as in older children, similar definite results. The giving of calcium permits keeping the infants on cow's milk. The author has also employed Behrend's treatment, which consists in the subcutaneous injection of twenty c. c. of an eight per cent. solution of magnesium sulphate. The results were satisfactory, but the injections proved painful and frightened the older children.

Gangrene of the Leg Following Diphtheria.—E. B. Gunson (*British Journal of Children's Diseases*, August 1916) reports a patient who received 20.000 units of diphtheria antitoxin on two successive days. On the seventeenth day sudden pain in the popliteal space developed and the next day the limb was discolored and the patient suffered subsequently from spasms of severe pain referred to the right popliteal region, and this region was extremely tender to the touch. The limb was of a lower temperature than the left and a ring of edema appeared about one and a half inch below the knee at the site of discoloration. On the twenty-second day, dry gangrene of the right small toe developed, which, by the thirtieth day had included the whole of the right leg below the knee joint. Later the limb was amputated about the middle of the thigh, and it was found that the popliteal artery was completely occluded by a thrombus extending for a distance of two inches above the bifurcation of the artery.

Complement Fixation in Pulmonary Tuberculosis.—Alfred Meyer (*Medical Record*, August 5, 1916) describes tests made in forty-eight cases with positive sputum, using Miller's antigen with positive results in all but two cases, ninety-six per cent. This is in accord with the findings of Baldwin with ninety per cent., Craig with ninety-six per cent., and Radcliff with eighty-nine per cent. positive tests.

Serum Reactions in Cases of "Enteric Fever."—Ernest Glynn and E. Cronin Lowe (*Lancet*, August 5, 1916) employed Dreyer's technic, using standardized agglutinable emulsions, and tested the reactions in a series of 300 unselected cases of enteric fever. Three thousand tests were made and the technic was found to be most satisfactory. Serums of men inoculated against typhoid and suffering from dysentery or some surgical condition gave no reactions against either paratyphoid organism. But all sera of convalescents excreting the paratyphoid bacilli agglutinated the corresponding organism in dilutions from one in 25 to one in 250. The titre in each form of paratyphoid infection was found to fall rapidly during convalescence. The typhoid titre, on the contrary, did not fall markedly in the majority of cases, but remained nearly stationary in the absence of typhoid infection, that is, in inocu-

lated subjects. No coagglutination occurred between paratyphoid A and B in convalescents, and typhoid vaccine or infection did not yield agglutins to either paratyphoid. On the other hand, the occurrence of paratyphoid B infection in typhoid inoculated subjects raised the typhoid titre. Titres for paratyphoid A averaged lower than for B, and hence a low titre was of more significance in the former than in the latter.

Hemihypertrophy.—Robert Hutchison (*British Journal of Children's Diseases,* August, 1916) reports the case of a boy five months of age in which the right arm and leg were appreciably larger than the left. The child was treated with citrate of potassium, but died subsequently. The post mortem examination showed a purulent pyelonephritis and an asymmetrical development of the trunk, limbs, and paired organs.

The Pathology of Weil's Disease.—H. Breitzke (*Berlin. klin. Woch.,* February 21, 1916) reports that detailed pathological examinations were made of the tissues in five fatal cases of this disease and the evidence pointed toward a general septic condition. Marked damage to the liver tissue was found in the form of swelling of the cell nuclei and edema of the pericapillary lymph spaces. The latter caused compression of the bile radicles. Multiple hemorrhages were present in the skin, subcutaneous tissues, mucous membrance of the intestine, and other parts of the body, including the brain and muscles. In the muscles, the hemorrhages were often focal and suggested a focal distribution of the infectious agent. The kidneys also showed hemorrhages with diffuse swelling and infiltration with lymphocytes, polynuclears and some eosinophiles. Similar pathological changes were observed in guineapigs which had been inoculated with material from the human cases. In the tissues of the pigs spirochetes were demonstrable, but these were found only twice in the human material, and then scantily. This indicated that the organism left the tissues early, just as it has been shown soon to leave the blood. In view of the anatomical changes found in these cases in man, the author suggests that the disease may lead to permanent damage to the organs, as evidenced by the prolonged convalescence in many cases of Weil's disease.

Abdominothoracic Tetanus with Prolonged Incubation Period.—P. L. Marie (*Paris médical,* July 8, 1916) reports the case of a man, aged thirty-two years, wounded by shell fragments in various places, including the left eye and the inner aspect of the left thigh. Two days later a prophylactic antitoxin injection was given, and shortly after the left eye was enucleated. One hundred and thirty days after the injury the patient began to experience lancinating pains in the abdomen, thorax, and lumbar regions, soon followed by continuous abdominal and lumbar muscular rigidity. All the wounds had healed rapidly except that on the left thigh, which was still discharging slightly through a small sinus. Administration of chloral hydrate, three grams daily, was begun, but the condition kept growing worse, and convulsions appeared, beginning at the waist and extending toward the feet. Soon after, alarming respiratory depression was noted, but later this passed off. An intense, permanent, and painless contraction of the lower part of the trunk and lumbar regions was observed, with a trace of trismus but absence of all rigidity of the lower and upper limbs. The reflexes were markedly exaggerated in the left lower extremity. No constitutional symptoms were noticed save slight pulse acceleration and a tendency to sweating. After the condition had remained stationary for ten days, in spite of repeated antitoxin injections and choral, x ray examination revealed a small shell fragment imbedded six cm. below the sinus already referred to, which was removed under local anesthesia. In the small accumulation of pus surrounding the projectile were found numerous kinds of bacteria, including Bacillus perfringens, long and narrow bacilli, diplococci, etc. Within a few days improvement set in, and complete recovery followed. In late tetanus, the portal of entry is almost always near the chief seat of the spasms; in this instance the virus evidently entered the thigh and traveled up branches of the lumbar plexus, finally reaching the cord at the corresponding level. The limitation of the disease to this area, its late development, and the favorable issue are ascribed to prophylactic tetanus antitoxin injections previously given.

Trichinosis. — Benjamin F. Salzer (*Journal A. M. A.,* Aug. 19, 1916) reports fourteen cases, occurring in an epidemic, studied carefully from the laboratory and clinical sides. In all of the cases the Kernig sign was present, all had edema of the face and all showed absence of the reflexes in the lower extremities. Almost half of the cases had edema of the lower extremities. The diazo reaction was present in all, and was proportional to the degree of eosinophilia present. Trichinæ were found in the blood in nine cases, in the spinal fluid in eight, in the stools of all, in a pleural exudate once, in the duodenum in one of two cases, in the pus of furuncles once; they were abundant in the milk and mammary gland of a nursing mother, absent from her uterus but abundant in the placenta, and they were absent from the urine in all cases. In one of the cases in which they were found in the spinal fluid, they were still present there three months after clinical recovery. Leucocytosis was found to diminish as eosinophilia increased, and the blood coagulation time was markedly prolonged in all cases. The feces were clay colored in all cases and this persisted in five which remained under observation. This was probably due to reduction of the bilirubin by living trichinæ. Cats, dogs and rabbits could be infected by injection or ingestion of materials from the human cases, such as pleural fluid and stools, and the organisms were found abundantly in the various tissues of these animals, including the brain and pancreas. The serum from recovered human cases removed the persistent eosinophilia in both man and animals, prevented infection in animals and, when mixed with infected material, rendered it noninfectious for animals when fed to them. Normal serum was without action in any of these particulars. In two very severe cases in the active stage, immune serum was found to have remarkable curative value, causing a prompt fall in the fever and removal of the eosinophilia.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

Joint Meeting of the Sections in Obstetrics and Pediatrics, Held Tuesday Evening, March 28, 1916.

Dr. GEORGE W. KOSMAK in the Chair.

The Correlation of Obstetrician and Pediatrist.—Dr. GEORGE W. KOSMAK observed that the obstetrician often concerned himself more with the care of the mother than of the infant, and dismissed the latter from his mind unless some startling abnormality occurred. The pediatrist was necessarily interested in the baby as such, and only too often was called in to care for a child with errors of growth and nutrition that might have been corrected or avoided earlier in its life. The subject of prenatal development was receiving increased attention, but practical application to the human subject had not yet been extensively made. Defective development had been ascribed to maternal intoxications of various kinds: in a diseased uterus even a healthy ovum usually failed to become properly implanted or nourished. The experiment of exposing fertilized eggs of certain fishes to oxybutyric acid and acetone had produced deformities of the most varied types which might lead to the belief that toxic products in pregnant women resulting from altered metabolism might account for departures from the normal of fetuses at birth, or even for defects manifested in later life. If obstetrician and pediatrist made more detailed observations on the human subject, their correlated work might contribute something more definite in this regard than was now generally known.

Dr. ROGER H. DENNETT said that in no other branch of medicine was there a specialty which called for both surgical technic and the peculiar mental attitude of the internist. The obstetrician was essentially a surgeon, the pediatrist essentially an internist. It was true that these two specialties had been combined, but no single individual had ever attained eminence in both. Judging from personal acquaintance among obstetricians, it seemed to him that their occasional practice of pediatrics was not only distasteful, but that it was thrust upon them by force of circumstances and tradition. It had been the custom for the obstetrician to take care of newborn babies from birth until the second, third, or fourth week of life, and the pediatrist had been the consultant only, called in when things went extremely wrong. This was true both in private practice and in the charitable hospitals among the poor. In New York city there was not, to his knowledge, a public lying-in service nor a private obstetrical institution where newborn babies were visited each day by a pediatrist, just as the mother was cared for by an expert.

There could not be any question that the study of congenital diseases was one of the most neglected and, at the same time, most important phases of medicine. Not only the mortality but the morbidity should be considered. There were three reasons why pediatrists should have infants under their care from birth: 1. Perhaps the most important, he should have the opportunity to study the much neglected subject of diseases of the newborn, since only in that way could this practically unexplored field be investigated; 2, the mortality could in all probability be enormously lowered if proper attention were given to these diseases; 3, the morbidity and its peculiarly distressing accompaniments might be lessened during the first year by preventing many cases of malnutrition and gastrointestinal disturbance.

The subject of early mortality from congenital disease was now undergoing a thorough investigation by the Bureau of Child Hygiene of the New York board of health and they were showing some startling statistics. For instance, 40.3 per cent. of the deaths under one year were shown to be due to congenital disease, whereas the deaths from respiratory or diarrheal disease were little more than half this number, twenty-three per cent.; further, seventy per cent. of all deaths due to congenital disease were due to causes that could be classed as preventable, forty-eight per cent. occurring in the first ten days of life. There could be no more convincing argument as to the urgent need of greater study of congenital diseases and diseases of the newborn.

On the subject of morbidity, statistics were less available, and it was necessary to depend to a certain extent on the mere opinion of the pediatrist. It was doubtful if there was a pediatrist present who had not the deepest conviction that at least fifty to seventy-five per cent. of his cases of difficult feeding could have been averted had he had the opportunity of supervising the infant from birth.

Even though it might be disputed whether the obstetrician should turn over to the pediatrist all his infants at birth, there could be no question that both the morbidity and the mortality might be lowered by doing so at two weeks of age. When the obstetrician discharged the mother, it would seem advisable that he recommend that a pediatrist be consulted for a thoroughly physical examination of the child and for purposes of obtaining dietetic and hygienic advice for future use. The follow up work now being done by the Babies' Welfare Association was a start in the right direction so far as public institutions were concerned. Most of the lying-in hospitals in the city reported the discharge of their obstetrical patients to this association which saw that the milk stations and a visiting nurse from one of the charities, in the neighborhood of the patient, did all that was necessary to get the baby started right in life. Last year 4,000 were cared for and the numbers were growing as the association was becoming known.

The proper correlation of the pediatrist and the obstetrician could best be brought about, 1. by giving as much attention to the appointment of a pediatric staff of lying-in hospitals as was given to the appointment of an obstetrical staff; 2, the pediatrist, once having been appointed, should make his daily rounds and study and observe his cases

from a clinical, laboratory, and pathological standpoint as he did now in his own children's and babies' wards; 3, the obstetrician should educate the laity to expect that his duties would be ended, as far as the infant was concerned, after it had been washed and dressed, with the possible exception of the care of the cord, and, 4, if the obstetrician did care for the infant as well as the mother up to the time that the mother's convalescence was completed, he should recommend that the infant be then put in the care of a pediatrist.

The Need and Value of Systematic Prenatal Care.—Dr. Ralph Waldo Lobenstine declared that in no field of preventive medicine was there to be found a greater opportunity for accomplishing such far reaching results as in prenatal care, which, to be of real value, must be systematic, intelligent, and untiring, and must begin with the perfect understanding and cooperation of the expectant mother. There was a terrible lack of real oversight of the parturient in the city of New York, largely due to the failure to apprehend the consequences of neglect. Prenatal care prevented, or at least lessened the frequency of many of the serious complications of pregnancy and many unnecessary maternal deaths; it better prepared the mother for labor and lessened invalidism and, finally, it had a deep influence upon the welfare of the infant. It was truthfully stated that ninety per cent. of American women were without proper prenatal care; in consequence, the loss of infant life was very high during pregnancy, labor, and the early post partum weeks, while between 15,000 and 20,000 women lost their lives annually from causes directly or indirectly attributable to child bearing.

Health statistics were particularly difficult to deal with in this country because of the incomplete registration area; in the registered areas there were to be found fairly accurate mortality statistics, but the birth records were still incomplete and the stillbirth records far from trustworthy. Improvement in the statistics of stillbirths would be favored by the adoption of some such law as the English Notification of Birth Act, which would further the development of better medical prenatal supervision. If these statistics were accurate and available, many lessons would be learned to the betterment of the human race.

About 80,000 infants died in utero from antenatal causes, and to this number must be added the great number of spontaneous abortions, of which there were no records and which were more or less dependent on the same causative factors. In New York city alone there were reported to the department of health in 1915, 6,419 stillbirths and 5,062 deaths under the age of one month. These early deaths were dependent on the same causes that were responsible for the intrauterine death of the fetus. All too often the child was physiologically unfit to maintain an independent existence. Both intrapartum and intrauterine mortality could be greatly reduced by proper measures.

The more common antenatal causes were syphilis, alcohol, renal and cardiac disease, sexual excess, deficiency in food supply of the mother, subnormal state of father or mother at time of conception, fatigue, and bad physical environment during pregnancy. The less tangible antenatal factors were gonorrhea, heavy use of tobacco and opiates, and the complex toxemias of pregnancy, the lower grades of which received far too little attention from the obstetric attendant, as they were often responsible for conditions of malnutrition, acidosis, and probably hemorrhagic disease in the infant. The evil effects of overfatigue, particularly when repeated, were well known.

The ultimate blame for the present high mortality in both mother and child was to be attributed to the following conditions: Ignorance or indifference on the part of a large section of the community in matters concerning parturition, poverty, insufficient obstetric training of the general practitioner, the midwife question, and lack of adequate prenatal care The remedy was to be found in publicity without exaggeration, general improvement in social conditions, elimination of the midwife, adequate, practical, and safer medical attention, greater hospital facilities, and more adequate home nursing. The system of training, almost universally prevalent in this country, afforded the average doctor a scandallously small amount of practical obstetrical experience, either before or after graduation. The general practitioner who by choice or by fate engaged in confinement work among the very poor, was deserving of the deepest sympathy.

Every woman should find it possible to obtain regular, systematic, prenatal care during the greater part of her pregnancy, there should be more clinics really doing prenatal work in fact and not only in name, and there should be closer cooperation of all the various agencies engaged in welfare work, and particularly an ever increasing widening throughout the country of the work of the visiting nurses, which was admirable, although the scope of their activities was not yet fully appreciated. The best solution of the question of prenatal care of the poor parturient woman might prove to be some form of industrial insurance. When the need and value of systematic prenatal care were more fully understood, the mortality statistics would be lowered, the home would become a better place, and the standard of community life would be advanced.

Accidents and Disease of the Early Weeks.—Dr. L. E. La Fetra said that injuries to the infant, as the result of prolonged labor, difficult forceps extraction, or abnormal presentations, might be grouped as affecting the head, the neck, and the extremities. Serious injuries to the head were those that resulted in intracranial hemorrhage. The loss of the sucking reflex was a most important sign of serious brain lesion. The commonest result after recovery from brain hemorrhage was spastic paralysis of one side of the body or of both lower extremities, and when more than two extremities were involved there was nearly always mental impairment. Immediate operation should be done if the hemorrhage could be localized.

Of the diseases and disorders to which the newborn infant was subject, among the congenital defects the most important was heart disease. Congenital hypertrophic stenosis of the pylorus was also important. Spina bifida, with or without

meningocele, added gravely to the prognosis in proportion to its size and the accompanying conditions. Cleft palate and hare lip added to the difficulty not only of feeding but of keeping the mouth clean and of preventing respiratory complications. Another defect was club foot. Constitutional disease was shown in hereditary syphilis and also by sclerema, general debility, chondrodystrophy and mongolism. Cretinism was not evident during the early weeks.

Among the acquired diseases, most important in the early days were acute infections. These included gonococcus ophthalmia and vaginitis, though the former could be entirely prevented if physicians were careful about instilling nitrate of silver. Erysipelas was not frequent, but was peculiarly fatal to young babies. Tetanus was formidable, but much less so since its antitoxin was used intraspinously. Of recent years sepsis in the newborn had become an important chapter of the increasing knowledge of infantile diseases. It might be caused by a great variety of germs such as the pyogenic cocci, the diplococcus of pneumonia, the colon bacillus, Bacillus pyocyaneus, the influenza bacillus, and the bacillus of Friedländer. In rare instances the infant was born septic, or became infected through aspiration of infected liquor amnii. The umbilical cord was the most frequent entrance port for sepsis, and next in frequency was the skin. The mucous membrane of the gastrointestinal tract was frequently the port of entrance. Because of the undeveloped condition of the skin and mucous membrane, the newly born were exceedingly susceptible to septic infection, and the younger the child the less the resistance so that the premature infant was most easily attacked. Breast fed children were attacked less often than those artificially fed and this was explained on the basis of the transmission to the baby of alexins through the mother's milk. In the treatment of sepsis, prophylactic measures were the best. After the condition had arisen, in addition to proper feeding, airing, and nursing, all the avenues of elimination should be encouraged. The most promising treatment was either transfusion, or the injection of normal blood or serum.

In the treatment of pyloric stenosis a careful trial of dietetic and medicinal measures should be made before deciding upon operation. The important points for deciding to operate were progressive loss in weight, lack of food residue in the stools, and prolonged retention of food in the stomach. Among the surgical procedures, the Rammstedt operation of partial pyloroplasty was probably the best. It should be emphasized that the aftercare of operations was exceedingly important.

Comparative Value of Methods for Treating the Umbilical Stump.—Dr. John O. Polak said that it was through the umbilical cord that the majority of infections of the newborn child took place. Made up as it was of bloodvessels which communicated directly with the fetal circulation, the slightest breach in technic in managing the cord stump which would allow the entrance of bacteria into these vessels produced a morbidity and in some instances a mortality for the infant. Satisfactory methods of treating the navel cord were indicated by, 1, the temperature of the child during the desiccation period; 2, the degree of icterus and the time of its disappearance; 3, the day on which the slough separated; 4, the condition of the stump after separation; 5, the frequency with which hernia followed; and, 6, the influence which the particular method of treatment had on the body weight of the infant. The ancients anticipated the danger attending umbilical infection by severing the cord with a hot iron. At the Long Island College Hospital during the last four years four methods had been given a trial. In the first series the cord was cut at a distance of seven or eight cm. from the umbilicus, tied near the distal end, and then turned over and tied a second time proximal to the first ligature, the loop of the cord being wrapped in alcohol soaked gauze and a belly band sewn on. The baby did not get a full bath until the cord dropped off, but the gauze and alcohol dressing was renewed every day or two. Later, the single ligature of the cord was employed. In another series the method suggested by Dickenson was employed, the technic of which was as follows: The cord was clamped at birth and cord and clamp wrapped in sterile gauze until the obstetrician had attended to the needs of the mother; then, after fresh gloves had been donned, an incision was made through the amniotic covering at the skin margin and the vessels were isolated and ligated with fine iodized catgut; the cord was then cut away distal to the ligature, the vessels were allowed to retract, and the skin margin was closed with sutures; a sterile dressing was applied and the binder sewn on. Since last June, this method had been modified and made less surgical; at birth the cord was clamped from five to ten cm. from the navel, and the child put aside until the mother had been returned to bed, when the clamp was removed, the cord stripped of its jelly, and a fine nosed Kelly clamp placed at the amniotic skin juncture; when this was removed an iodized catgut ligature was firmly tied in the crease, and the cord cut away with a knife.

Hemorrhage from the cord after careful ligature and blood in the stools and vomitus were often regarded as signs of hemophilia. A systematic daily examination of every infant's stool by the resident of the hospital often disclosed the first sign of blood, and not a few babies' lives had been saved by this daily inspection, for with the first appearance of blood an injection of whole blood from the mother was given subcutaneously to the child which had usually checked further bleeding. Serum was not only difficult to obtain, but had to be checked up by a Wassermann before its employment.

The mouth of the newborn was a common avenue of infection. The epithelium of the tongue and buccal cavity was the infant's sole protection against infective processes and should not be removed by the overdiligent nurse who attempted to cleanse the mouth of mucus with a gauze covered finger. Primary mucus could be got rid of by inversion of the child and stroking of the neck and thorax from the abdomen toward the head, stripping the neck of mucus, or by aspiration with a catheter. For two years washing the baby's mouth before and after nursing had not been done.

Experimentation with silver, protargol, and argyrol solutions had shown that a twenty-five per cent. solution of argyrol in each eye at birth gave

good protection against gonococcic conjunctivitis, without danger of ulcer.

Care and Feeding during the First Month.—Dr. GODFREY R. PISEK said that it would be generally conceded that the first month of the infant's life was the most important one from the standpoint of care and feeding. The latest mortality statistics for the first month of life in greater New York showed that during the first eleven weeks of 1916 fifty per cent. of the deaths occurred in the first month of life, which high mortality could be lowered by active measures of prevention and correction. Attention was called to certain basic principles underlying the feeding of infants in the first month of life which, if transgressed, were apt to bring trouble or even disaster.

The attitude of pediatrists had changed considerably in the last five years in regard to the feeding of infants, but there was a unanimity of opinion that breast milk was the infant's birthright which it should not be denied. But in spite of this and of the fact that eighty-five per cent. of infantile deaths were among those artificially fed, they were still being removed from the mother's breast for insufficient reasons by the physician or nurse. In many cases insufficient breast milk could be supplemented by one or two bottles of artificial food a day. In this way the supply could be kept up, at the same time allowing a period of freedom for the mother. In his case book the records showed that thirty per cent. of the children in his care were receiving mother's milk only, 48.8 per cent. were on the bottle, and the breast, and 22.5 per cent. were receiving the bottle exclusively. Blameworthy were those who removed the baby from the breast, not because of the accepted contraindications for nursing, but basing their decision on the fact that no milk had appeared in forty-eight or seventy-two hours, or on one hasty and inaccurate examination of the milk, or because there was some vomiting after nursing, or because of an occasionally abnormal stool, or because the mother or attendants thought the breast milk did not agree.

Every effort should be made to have the baby receive breast milk alone, or at least part breast milk, during the first month of life. Even a small amount of breast milk aided in the digestion of cow's milk. Complete emptying of the breasts was the best method of assuring a good supply, and yet this simple means was frequently overlooked. If artificial food was necessary, it should be low in fats and proteins, but high in sugar, until after it was certain that the infant had adapted itself to cow's milk, when the strength in the other elements could be increased. Mixed feeding should not be introduced in the first month if at all avoidable, as greater resistance was secured after a month or two on the breast alone. If it had been satisfactorily determined that the amount of secretion was constantly deficient, then a bottle feeding should follow each nursing period. The care of the pathological newborn would extend to beyond the limits of the allotted time, and any unsuccessful attempts at artificial feeding should be at once discontinued and the help of a wetnurse secured.

Should circumstances demand that the baby be artificially fed during its first weeks of life, the physician should realize that this was the most sensitive and precarious period in the baby's existence and that one mistake might endanger the child's life, whether this was in the food itself, in the mixture, or in its preparation. Simplicity in feeding was rapidly gaining ground, and if they kept in mind the caloric needs, the protein needs, and at the same time adapted the food to the digestive capacity of the particular infant, success was quite assured. The caloric requirements were not to be fulfilled until the end of the second week. Boiling the milk in the first weeks was often necessary to prevent the formation of tough curds. A gain in weight could be expected only when the food was given in utilizable form and in such quantity that the caloric needs (100 to 120 calories to the kgm. of body weight) had been supplied. The amount of food allowed depended on the period selected and should be calculated on a twenty-four hour basis.

At no time was it so necessary to inculcate regularity of habits and to abide by the laws of hygiene as in the first month of the baby's life, and obstetrician and pediatrist should join hands, for on them devolved in a large measure the responsibility of reducing mortality among the newborn.

Syphilis in Mother and Infant.—Dr. J. R. LOSEE said that there were many theories on the transmission of syphilis from the parents to the offspring, but for the present it was necessary to reason from the history and clinical findings. Many men who had had syphilis and who were very thoroughly or only partially treated, married and had healthy children; on the other hand, the wives of men under the same conditions of treatment and in apparent good health, gave birth to macerated fetuses and syphilitic children. There was no definite means by which a parent, subject to latent syphilis, could be assured that all his children would be born free from manifestations of the disease. The paternal theory, that the spermatic fluid affected the ovum which went on to the development of a fetus which in turn affected the mother, seemed hardly possible. There was no doubt that several cases of pure spermatic infection had occurred, as many women were affected directly after marriage. The maternal theory, in which the mother was affected primarily and the fetus secondarily, was quite probable and easy to explain. The fact that a patient denied symptoms of primary or secondary syphilis, when questioned after being delivered of a macerated fetus, and had a positive Wassermann reaction, did not prove that they were not present some time before or during pregnancy. As most of the stillbirths from syphilis took place in the latter months of pregnancy, it was fair to assume that the fetus was infected from the mother through the placenta, but whether the placenta could transmit spirochetes without showing pathological evidence was an unanswered question, so that they might draw some relation between the nonsyphilitic children of syphilitic parents and the normal placenta.

A consideration of the effect of syphilis on the offspring included both the transmission of the infection in its active form, in which the fetus either died in utero, or was alive and showed symptoms during the first year, and the transmission of the latent form

of the disease, in which the child was normal in every respect at birth and during the first year, but acquired typical syphilitic lesions later in life. Comparatively few infants born of syphilitic parents went through life without at some time presenting symptoms of the disease. Maternal syphilis had always been considered to play a considerable part in the etiology of abortions, macerated fetuses, premature births, and stillbirths, but it was fair to assume that the same etiological factors were present which had been said to cause abortions in nonspecific women. Intrauterine death of the fetus from the sixth month to term had long been known to be due in most instances to syphilis, and thirty-five to forty per cent. of stillborn children were due to syphilis.

Letters to the Editors

SOME CHARACTERISTICS OF POLIOMYELITIS.

New York, *August 28, 1916.*

To the Editors:

I was assistant demonstrator of diseases of children at Jefferson Medical College, Philadelphia, from 1896 to 1901, and therefore saw many cases of infantile paralysis among children; I have also seen yellow fever in the West Indies. The similarity of the spread of these two diseases in epidemics has been impressed on me. Both are filth diseases, both flourish in hot weather and cease in cold weather, owing to the fact that the mosquito, being the carrier of yellow fever, perishes in cold weather, and I believe the same will be found in infantile paralysis. Both diseases spread more rapidly in hot, humid weather, slow down in clear, cool, windy weather, owing to the activity or quiescence of the mosquito, and the fact must be taken into consideration that the early part of the summer in this latitude was extraordinarily wet and that there were more mosquitoes than there had been for years. I find also that in the poorer parts of greater New York, where the disease has flourished, there are proportionately fewer doors and windows screened against flies and mosquitoes than in other sections. This is important to know, as after the first case occurs the opportunity of mosquitoes to bite infected persons is greater in proportion to the scarcity of screening. While I believe that any biting insect, such as the fly, bedbug, roach, or flea, will carry the disease from person to person, also sanitation will decrease the spread, as it destroys filth and also these pests, as it does in bubonic plague and yellow fever, but the mosquito is not destroyed in toto by sanitation as it is employed today in the temperate zone, unless mosquito destruction is striven for also. The disease spreads in the houses of the wealthy and well to do in spite of sanitary measures, and is not always confined to the poorer and unsanitary parts of cities and towns. It will be found that the disease flourishes in places where the mosquito is most plentiful. In some parts of New York, where there are thousands of children to the block there are no cases—also no mosquitoes; while in places with fewer children to the block there are many cases—also mosquitoes. If you read the history of the yellow fever epidemic of 1877 in the Mississippi Valley, starting at New Orleans, you will be startled at the similarity of the history of that epidemic to the present epidemic of infantile paralysis, starting from greater New York as a base, and spreading more to the small suburban towns and cities by railroad and steamer, where also there are more mosquitoes than in the larger cities, just as yellow fever spread in the small towns of the Mississippi Valley. A person would leave New Orleans, fleeing from the plague, already infected by yellow fever, would stop at an uninfected town 100 miles away, thinking he was safe, be taken down with the disease, be bitten by mosquitoes, and when these mosquitoes had bitten other people, the disease became epidemic in that town. Hence the shotgun quarantine of towns and villages against travelers and strangers.

Thus, a mosquito biting a child fleeing from New York, and already infected with the disease when it left New York, bites other children, and there are more cases. They also bite adults, but adults with few exceptions are immune and are not affected. Now if medical men followed the example of the army officers in Cuba and had children already ill with the disease bitten by mosquitoes in a jar, and then had the hand and arm of a monkey introduced into that jar and bitten by the same mosquitoes, as was done in yellow fever, the matter would soon be proved. (If this has been done I have never heard of it.)

In my opinion, after all sanitation is accomplished and cities and towns are cleaned up, flies swatted, etc., the patient should at once be placed in isolation *under a mosquito curtain,* so that no mosquitoes could reach him, and the mosquitoes should then be free to bite other children not yet ill. An active mosquito campaign should then be started, just as is done in the tropics in yellow fever. It must not be forgotten that this season has been very favorable to the propagation of mosquitoes, and to my mind this explains the spread of infantile paralysis in the Catskills, in Orange and Sullivan counties, New York, and in many towns in New Jersey, where sanitation is good and which ordinarily are the most healthy places in the country. This also explains its spread along the coast and in the houses of wealthy people living on splendid country estates, where every precaution is taken, but there is no mosquito destruction. One case in the neighborhood is all that is needed to spread the disease.

Chas. S. Braddock, Jr.,
Late Chief Medical Inspector,
Royal Siamese Government.

AGGLUTINATION TESTS: ERRATA CORRECTED.

Brooklyn, N. Y., *August 30, 1916.*

To the Editors:

In your review of my article from the *Medical Record* for August 12th, in an effort to be brief, unavoidably perhaps, you fell into error in several important respects.

You state that agglutination tests "were unsatisfactory," whereas the figures given show that with cases of variola the blood serum specifically clumped, in dilutions as great as one to 160, the cultures of the bacillus from variola. The same was the case with the bacillus cultivated from vaccine virus, when tested against the blood serum of animals used to produce vaccine virus. Your statement evidently was based upon the fact brought out that the bacillus derived from vaccinia virus was agglutinated by variola serums to a slightly greater extent than was that derived from cases of variola. Also, I think you should have stated that all controls were negative, and that the tests indicated distinct differences in the nature of the bacilli derived from varicella compared to those from variola and from vaccine virus. Further, that in regard to the variola bacillus, "the longer this organism is cultivated the nearer does its relationship become to the vaccinia organism."

A brief summary of the findings of my article follows: 1. By the technic given, the bacilli described may be seen in large numbers in smears made from cases of variola, from vaccine vesicles, and from vaccine virus (especially Noguchi's pure culture virus). Likewise a similar shaped organism is to be found in smears from vesicles of varicella cases. 2. By the special method of regularly watering Löffler serum cultures (of the organism in question) with a mixture of lime water and bouillon, the bacilli described can be developed (in approximately ten days) from, a, Cases of variola (vesicles and blood); b, vaccine vesicles; c, vaccine virus (including Noguchi's pure culture in rabbit testicles); d, varicella vesicles (not forgetting the evidence that this organism shows points of distinct difference from the preceding). The minute bipolar bacillus of the original material develops to a much greater size when cultivated as described. 3. Specific agglutination was obtained in dilutions of specific serums, as great as one to 160, of the bacilli from variola and vaccine virus. 4. Specific complement fixation tests were obtained with antigen made from bacilli from variola and vaccine virus, when tested against the blood serum of variola cases and recently vaccinated persons. 5. Differences between the bacilli derived from variola and varicella were sufficient to establish the two as distinct organisms.

H. Greeley, M. D.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

On Modern Methods of Treating Fractures. By Ernest W. Hey Groves, M. S., M. D., B. Sc. (Lond.), F. R. C. S. (Eng.); Surgeon to the Bristol General Hospital; Consulting Surgeon to the Cossham Hospital, etc. New York: William Wood & Co., 1916. Pp. xii-286. (Price, $2.75.)

This is a small compact work, usually well supplied with photographs and skiagraphs, which takes up modern methods under three main heads, massage and mobilization, extension, and operative measures, although it deals mainly with the last. The author considers that both absorbable bone pegs and plates with short screws are unsatisfactory, while encircling wires are of use only in very oblique fractures. Mechanical efficiency, he avers, can be obtained by the use of long plates and transfixing screws or bolts or by long intramedullary pegs of metallic magnesium which act as a powerful stimulus to callus formation. Extensive experiments on animals are described, which show that the periosteum is the product and not the producer of bone and that the callus grows mainly from the outer or periosteal surface of the living bone, but also partly from the medullary surface and cut ends.

The Pathology of Tumors. By E. H. Kettle, M. D., B. S. (Lond.). Assistant Pathologist, St. Mary's Hospital, Assistant Lecturer on Pathology, St. Mary's Hospital Medical School, etc. With 126 Illustrations. New York: Paul B. Hoeber, 1916. Pp. viii-224. (Price, $3.)

In the present wealth of our literature on tumors, a new book dealing with the subject should have some special reason for its appearance. The author should have something new to present to specialists, or some advantage in the way of presentation, especially for students. This volume is apparently based on material gleaned from other textbooks, or verified in clinical and laboratory work, and does not bear the stamp of an original investigator in the subject. The descriptions are too brief for any one seeking intimate knowledge of any particular tumor such as we should find by referring to one of the standard books on the pathology of neoplasms. The book's value is chiefly that of printed notes of the author's lectures, illustrated with good pictures of sections, and it could well be utilized by a student hearing those lectures. As a contribution to the subject of the pathology of tumors, the book has only limited value and an interest chiefly local.

Venesection. A Brief Summary of the Practical Value of Venesection in Disease. For Students and Practicians of Medicine. By Walton Forest Dutton, M. D., Fellow American Medical Association; Member Medical Society of the State of Pennsylvania, etc. Illustrated with Several Text Engravings and Three Full Page Plates, One in Colors. Philadelphia: F. A. Davis Company, 1916. Pp. viii-220. (Price, $2.50.)

This seems rather a pretentious volume for a subject of such comparatively slight interest as venesection, but it is obviously the intent of the author to make this therapeutic procedure more popular than it now is. We cannot, however, read the scores of conditions in which he advocates venesection as a part of the treatment without the feeling that he has become unduly biased in its favor. This feeling of bias is made the stronger when we scan the other measures of treatment which he often advocates along with bloodletting, for if he really believed that the latter was the most important element, he would scarcely recommend such a host of other remedial measures as is often the case. He describes the technic of venesection, but his method does not seem to be the best or the simplest for the general practitioner, although it may be entirely satisfactory in hands which have become thoroughly used to it. Reference is frequently made to leeching, wet cupping, and the use of the artificial leech, but no description of the technic of any one of these procedures is given. The book, however, is not devoid of interest or value, for the author has given a most excellent historical review of the practice of venesection from the dark ages down to the present time; but so far as making out a strong case for the value of bloodletting, he seems to have left the impression that he would have it employed rather indiscriminately in a host of different conditions for which indications are not at all clear.

Ultraviolet Light by Means of the Alpine Sun Lamp. Treatment and Indications. By Hugo Bach, M. D., Bad Elster, Saxony, Germany. Authorized Translation from the German. New York: Paul B. Hoeber, 1916. Pp. 114. (Price, $1.)

This small volume is replete with points of practical interest. A description of the new model (1913) alpine sun lamp as designed by the author, Brieger, Nagelschmidt, Koenig, and Hagemann, is followed by a comparison between its effect and the effect of sunlight. Instructions as to technic, method of application, duration of treatment, intervals between treatments, etc., are given in detail; also how it can be employed in diseases of the respiratory tract—inhalation. The immediate and remote effects of the treatment are enumerated, and the final chapter is devoted to case reports and to a résumé of the diseases in which this method of treatment may be used to advantage.

Interclinical Notes

There are many articles to interest the educated physician in the *Scientific Monthly* for September, e. g., The Scientific Investigation of Cancer, by Dr. Leo Loeb; Substances without Chemistry, by Dr. John Waddell; Science and Feminism, by Dr. Robert H. Lowie and Dr. Leta Stetter Hollingworth; and The Origin and Evolution of Life upon the Earth, by Dr. Henry Fairfield Osborn. To an educated man with a little imagination, the *Scientific Monthly* offers ten times the relaxation provided by the story journals, to say nothing of the chance of giving some hint on disease or prophylaxis that may make the reader famous.

* * *

If we had the power to award a gold watch for the best annual epigram, we think that this year's timepiece would go to F. P. A., of the *New York Tribune,* in honor of the last quatrain in his translation of Horace, II, 2, which appeared August 31st:

So, Sallust, let them gather gold who may!
The graft is bad. I prithee, don't begin it.
A well filled purse, as Chesterton might say—
There's nothing in it.

* * *

This Journal was the first, we believe, pointedly to direct the attention of physicians to the importance of the teeth as a factor of health. Dr. Matthias Nicoll writes on the subject of oral hygiene in the handsome *Outlook* for August 23d. "Happily," he says, "the medical profession has at last come to realize that the field of dentistry is not isolated or independent, but touches at many points the field of general medicine and surgery." Yet we remember well the day when a similar remark would have evoked from the physician a sneer to the effect that the dentist had better attend exclusively to his own pathological researches.

* * *

Health! exclaims *Leslie's* for August 24th. The biggest enterprise ever projected for the prevention of disease is the Institute of Hygiene and Public Health to be established by the Rockefeller Foundation in connection with the Johns Hopkins University at Baltimore. It is intended that the new institute shall make as notable and original a contribution to humanity as the now world famous Rockefeller Institute for Medical Research has made in its field. The campaign of the foundation against the hookworm disease, and more recently the battle of the American Red Cross with typhus in Serbia, have convinced the directors of the foundation that what the world needs is men scientifically trained for the promotion of public health, sanitation, and preventive measures generally. The director of the institute is to be Dr. William H. Welch, professor of pathology at Johns Hopkins University, and all the facilities of this great university and the Johns Hopkins Hospital will be at the disposal of the new school. Every city and State which has heretofore found difficulty in securing health officials adequately equipped for the ad-

ministration of scientific sanitation will be benefited by the new institute. The Rockefeller Foundation is to be commended for its original and far seeing contribution to the public health, especially in the present investigation of the causes of infantile paralysis, the results of which will be shared by all the world.

* * *

The *Survey* for August 5th tells how just after millions of dollars worth of munitions of war had exploded only a mile away on July 30th, the patients on Ellis Island sank again quietly to sleep. Although shrapnel and bullets rained down upon buildings and grounds; windows were blown out; locks and hinges were wrenched away; tiles loosened in patches upon the roofs; window panes and transoms were either pulverized, bitten into, or jarred into patterns like all over lace; yet out of more than 500 persons on the island, not one was seriously injured.

Meetings of Local Medical Societies

Monday, *September 11th.*—Roswell Park Medical Club, Buffalo; Williamsburg Medical Society, Brooklyn.

Tuesday, *September 12th.*—Federation of Medical Economic Leagues of New York; Medical Society of the County of Schenectady; Newburgh Bay Medical Society.

Wednesday, *September 13th.*—Alumni Association of Norwegian Hospital, Brooklyn; Medical Society of the Borough of the Bronx; Richmond County, N. Y., Medical Society; Dunkirk and Fredonia Medical Society.

Thursday, *September 14th.*—Gloversville and Johnstown Medical Association; Physicians' Club of Middletown; Blackwell Medical Society of Rochester; Buffalo Ophthalmological Club; Jamestown Medical Society; Society of Physicians of Villages of Canandaigua.

Friday, *September 15th.*—Mount Vernon Medical Society.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending August 30, 1916:

Corput, G. M., Surgeon. Directed to proceed to New Orleans, La., when necessary to transact station business.

Currie, Donald H., Surgeon. Granted four days' leave of absence on account of sickness, from July 26, 1916.

Foster, M. H., Surgeon. Directed to proceed to Philadelphia, Pa.; Camden N. J., and Wilmington, Del., to observe precautions taken to prevent interstate spread of poliomyelitis.

Fricks, L. D., Surgeon. Bureau letter dated July 25, 1916, amended so as to grant three days' leave of absence from August 12, 1916.

Gassaway, J. M., Senior Surgeon. Directed to proceed to Evansville, Ind., to take temporary charge of Marine Hospital during the absence of Surgeon J. H. Oakley.

Lanza, A. J., Passed Assistant Surgeon. Granted two days' leave of absence on account of sickness, August 19 and 20, 1916.

Leake, J. P., Passed Assistant Surgeon. Directed to proceed to Alexandria, Va., for investigation of a suspected case of poliomyelitis.

Liddell, T. J., Assistant Surgeon. Directed to proceed to New Orleans, La., for observation of method of fumigation of vessels by cyanide gas; thence to Mobile Quarantine Station and assume charge.

Lloyd, B. J., Surgeon. Bureau telegram dated August 5, 1916, amended to grant seven days' leave of absence from August 8, 1916.

Nute, A. J., Acting Assistant Surgeon. Directed to proceed to Greenwich, Conn., for examination of detained alien.

Safford, M. V., Assistant Surgeon. Relieved from duty in New York city and ordered to rejoin station at Boston.

Smith, L. H., Assistant Surgeon. Granted one day's leave of absence, August 20, 1916.

Stiles, C. W., Professor. Directed to deliver an address on public health at Community Meeting at Emmitsburg, Md., September 2, 1916.

Von Ezdorf, R. H., Surgeon. Directed to proceed to Washington, D. C., for conference regarding field investigations of malaria.

White, M. J., Surgeon. Directed to proceed to Brunswick, Mo., to investigate reported outbreak of typhoid fever.

Wilbert, M. I., Technical Assistant. Detailed to represent the service at the meeting of the American Pharmaceutical Association at Atlantic City, N. J., September 5 to 9, 1916.

Births, Marriages and Deaths

Married.

Guilford-Gearing.—In New Bedford, Mass., on Thursday, August 24th, Dr. Henry M. Guilford, of Hartford, Conn., and Miss Bertha A. Gearing.

O'Leary-McEvoy.—In Newark, N. J., on Wednesday, August 16th, Dr. Daniel Vincent O'Leary, of Albany, N. Y., and Miss Mary Agnes McEvoy.

Silvey-Wilson.—In Waterbury, Conn., on Sunday, August 27th, Dr. Francis Leroy Silvey, of Albany, N. Y., and Miss Genevieve E. Wilson.

Wile-Work.—In Colorado Springs, Col., on Thursday, August 31st, Dr. Udo J. Wile, of Ann Arbor, Mich., and Miss Katherine A. Work.

Died.

Allison.—In Punxsutawney, Pa., on Friday, August 25th, Dr. Samuel C. Allison, aged eighty-six years.

Assenheimer.—In Far Rockaway, N. Y., on Thursday, August 24th, Dr. Augustus Assenheimer, aged sixty-seven years.

Baker.—In Lynn, Mass., on Tuesday, August 22nd, Dr. William H. Baker, aged seventy-two years.

Bergeron.—In Warren, R. I., on Monday, August 21st, Dr. Seraphin E. Bergeron, of Fall River, Mass., aged sixty-three years.

Boyle.—In Colon, Panama, on Tuesday, August 22nd, Dr. Stacy Watson Boyle, of Middlebury, Vt., aged twenty-nine years.

Byam.—In Rochester, N. Y., on Sunday, August 20th, Dr. Lucius W. Byam, of Mumford, N. Y., aged seventy-two years.

Dailey.—In Gloversville, N. Y., on Monday, August 21st, Dr. Lawrence J. Dailey, aged fifty-eight years.

Estabrook.—In Brookline, Mass., on Sunday, August 20th, Dr. Edward L. Estabrook, of Minneapolis, Minn., aged seventy-one years.

Fritchey.—In Philadelphia, on Friday, August 25th, Dr. John A. Fritchey, of Harrisburg, Pa., aged fifty-eight years.

Gay.—In Boston, Mass., on Saturday, August 26th, Dr. Warren Fisher Gay, aged fifty-one years.

McLaughlin.—In Stockton, Cal., on Tuesday, August 22nd, Dr. James H. McLaughlin, of Sutter Creek, Cal., aged fifty-four years.

Marple.—In Kennebunkport, Maine, on Wednesday, August 30th, Dr. Wilbur B. Marple, of New York.

Meggenhoffen.—In Chillicothe, Ohio, on Wednesday, August 23rd, Dr. Edward Meggenhoffen, aged sixty-three years.

Milton.—In Oakland, Cal., on Saturday, August 19th, Dr. Joseph L. Milton, aged forty-six years.

Morrison.—In Detroit, Mich., on Thursday, August 24th, Dr. John W. Morrison, of Greensburg, Pa., aged ninety years.

Newberry.—In Lizella, Ga., on Sunday, August 27th, Dr. M. J. Newberry, aged fifty-four years.

Sharp.—In Camden, N. J., on Thursday, August 24th, Dr. Ezra B. Sharp, aged fifty-five years.

Travers.—In Saratoga, N. Y., on Thursday, August 24th, Dr. Osmond J. Travers, aged sixty-five years.

Ward.—In Pennington, N. J., on Thursday, August 24th, Dr. John Wesley Ward, aged seventy-seven years.

Wireback.—In Pittsburgh, Pa., on Sunday, August 20th, Dr. Nevin H. Wireback, aged thirty-four years.

EPILEPSY.*

Recent Studies into the Cause and Pathology,

BY CHARLES A. L. REED, M. D.,
Cincinnati.

The mere fact that I, a surgeon, am asked to address you on epilepsy, heretofore presumably a topic belonging exclusively to the realm of internal medicine, is of itself a circumstance which would seem to call for some explanation. It is proper, therefore, for me to state that my identification with the subject was primarily practical and entirely accidental. It grew out of the fact that, for a number of years, I have been dealing in a surgical way with the causes of constipation as they exist in displacements, adhesions, distortions, and malformations of the intestines. It so happened that some half dozen of these patients presenting themselves in the course of several years had epilepsy,—a circumstance to which at the time I gave no attention. Then, later, it happened that these patients reported that they had recovered, not only from their constipation, but, much to my surprise, that they were well of their epilepsy. It was a short series of cases, but one hundred per cent. of apparent recoveries on the basis of even so short a series, recoveries from so recognizedly incurable a disease, was a coincidence that arrested my attention and prompted the hope that some tangible connection might be demonstrated between the constipation, between the intestinal states underlying the constipation, and the epilepsy —a connection so tangible that it might serve as a definite basis for subsequent treatment of the malady. It was with this approach to the subject, an approach at once accidental, independent, and unique, that I went afield to find such facts as might tend to the solution of this baffling problem of the ages.

The beginning was made in the clinical field. It was here that, starting with the always present constipation, obvious or masked, I found myself forced to give attention to various sequent phenomena which had not previously been taken into account or, if given consideration at all, had been accorded only a subsidiary relation to the disease. In this way, I speedily became convinced that infection, obviously originating in the intestines, was essential to a rational explanation of the conditions as I saw them. I even went to the extent of announcing this conclusion, arrived at deductively, long before the actual demonstration of what today must be recognized as its underlying facts. This conviction was so strong that I inaugurated a series of experimental studies by placing Dr. E. P. Hyatt, formerly of Syracuse University, in charge of my laboratory. These investigations, conducted under my direction and parallel with my clinical work, have led to certain developments which I look upon as being of so much importance that I have had no hesitation in laying them before the profession. In presenting them again today, I shall reverse the order by which the synthesis of the subject has been achieved in my hands, and shall accordingly begin by presenting its later developments.

The one fact of fundamental importance, the very last to be developed, is that we have found and are finding in epileptics an organism that we are not finding in nonepileptics. It is a rather large spore bearing bacillus, and may be procured from the blood, occasionally by direct smears, more frequently by culture. In the early stages of development, it may be recognized as a short, thick bacillus with blunt ends. Even in this stage, it is very motile and goes through various evolutions in the hanging drops. As it becomes older it assumes the form of a chain which, however, still manifests the characteristic motility. About this time the sporulation becomes evident and progresses relatively to the age of the organism, until finally, after the lapse of from twelve to fifteen days, the organism proper disappears, leaving the spores in great numbers to reinaugurate the cycle. The organism stains best to carbol fuchsin, although Abbott's spore staining method may best be employed to show both the organism and the spores. In consequence of the high resistance of the spores, the organism is immune to pure phenol.

This organism was subjected to experimental study on rabbits. Intravenous inoculation was practised with the result that the animals were attacked by convulsions that were typically those of epilepsy. The initial cry, the fall, the convulsion, the torticollis, the lateral nystagmus, all lasting from three to five minutes, followed by a period of stupor, and this in turn by a period of from a few hours to a few days of perfect health, characterized

*An address delivered before the Alumni Association of Syracuse University Medical School, Syracuse, N. Y., June 13, 1916.

the manifestations in rabbits, just as they characterize essential and typical epilepsy in the human subject. Animals in which the dose was very large died *in statu epileptico;* others in which it was smaller had a series of typical convulsions, after which they recovered, thus showing the ability of natural immunity to overcome the infection in the absence of a focus of continuous supply. In some instances the disease developed in rabbits after taking the organism through the mouth. In all cases in which the disease developed in rabbits, whether by inoculation or ingestion, the organism was recovered from the blood of the animals. It seems from this that our conclusion that the organism in question does bear a causal relation to epilepsy, in other words that it is Bacillus epilepticus, is justified by the entire conformity of our experiments to the law of Koch.

The extracorporeal existence and conduct of the organism have not been determined. The fact, however, that Hinkelmann has found in the mouth a phenol-proof spore-bearing organism with a morphology in its early stages analogous to that of Bacillus epilepticus in its early stages, prompts me to believe that the two may be identical. I have found Bacillus epilepticus in the small intestines, in the cecum, in the vermiform appendix, in the transverse colon, in the mesenteric and the mesocolic lymphatics, and in the blood of the same patient. It seems, therefore, that footprints of the organism can readily be traced from without inward. We have traced it from food to blood by way of the alimentary canal in rabbits. We have kept the spores alive but not active *in vitro* for four months —nonnutritive media being employed for the purpose. In view of all these facts and the additional fact that it is voided in the feces of both human and animal subjects, it seems that this spore bearing organism, like the spore bearing bacillus of tetanus, has its primary abiding place in the upper stratum of the soil. It is furthermore readily understandable how it may easily be carried from the soil to the mouth, how its resistant properties enable it to withstand the digestive ferments until it takes up its abiding place in the cecum, whence, under the pressure of colonic stasis, it is forced into the circulation.

This brings me to the next link in the chain of etiological sequence, the link, however, which was the very first to force itself upon my attention. It consists in the fact that constipation is the one clinical condition most constantly correlated with epilepsy and in the further fact that, underlying this epilepsy and this constipation is some form of mechanical interference with the fecal current. This mechanical interference, while constant in principle, is very variable in detail. Thus, I have found some form of ptosis constantly present. A large, flabby, and mobile cecum, generally well laden with semisolid fecal matter, is the usual condition. Then there are retardative angulations at the hepatic flexure, in the middle of the festooned transverse colon, at the splenic flexure, and at the redundant sigmoid. There are frequently found adhesions of both the ileum and the colon—especially near the terminal ileum—giving rise to what Sir Arbuthnot Lane calls "ileal stasis." There frequently exists ptosis of the stomach with adhesive exudate binding down the entire duodenum. These are the chief conditions which, singly or in numbers, are presented in the individual case, and for the relief of which judiciously selected surgical measures are required. I am not, however, discussing the details of therapy, medical or surgical; but I do wish to emphasize the fundamental etiological significance of mechanical stasis in epilepsy. I have found it in some form constantly present in over four hundred cases of which I have x ray records, and in nearly 2,000 cases of which I have otherwise recorded histories often verified by physical examination. I have said, "in some form," for in some instances the constipation is intermittent and recurrent; in other cases it is masked, by which I mean that "regular" daily movements are shown by the barium test to be retarded movements sometimes many days behind time; while in a few instances, possibly two per cent., I have encountered chronic diarrhea, due to deep infection, with resulting catarrhal conditions of the intestine, all following previous long standing constipation.

If, now, there is an organism, as I have shown; if that organism may enter the alimentary canal, as I have shown that it can and does; if it is forced from the alimentary canal into the circulation by the anatomical disturbance of mechanical stasis which are sequelæ that I have demonstrated to be present in one hundred per cent. of my cases; if these things are true the immediately consecutive stages of the pathological process intervening between absorption and convulsion become matters of interest. Here, however, we have to deal only with phenomena, clinical and pathological, which, in a general way, conform to the well recognized conduct of infections. Thus with the establishment of any systemic infection, we have toxemia, next, acidosis, and, finally, the superhydration otherwise called edema of various structures. The toxemia of epilepsy is shown by the constant tendency to a subnormal temperature and by the elimination of various toxic products in the urine. *Chronic acidosis, profound, always obstinate, often almost irreversible, exists in one hundred per cent. of epileptics.* It is but natural that acidosis of this character should be followed by edema especially marked in organs and structures upon which the primary infection exercises a selective action, just as Rosenow has shown that different strains of streptococci cause edema, often with pus forming results in different localities, as, for instance, the stomach, gallbladder, and joints, according to the predilection or "elective affinity" or "selective action" of the particular strain involved in the process. And so it would seem that Bacillus epilepticus exercises its terminal effects by producing a terminal deinsulating edema of the conduction paths of the brain, as in purely convulsive disturbances; or of both the conduction paths and the cortex, as in convulsions with psychic explosions. This process of selective action finds analogies in the terminal effects of various infections, as, for example, when the pneumococcus "selects" the lungs: the meningococcus, the meninges; the tetanus bacillus, the nerve trunks; or

the gonococcus, the mucous membranes. As a matter of easy and frequent observation, the edematous process in epileptics with advanced infection and profound acidosis may be seen in puffiness about the eyes and ankles, often associated with slight albuminuria, indicating a general process of which that in the brain is but one, although a primary and essential manifestation. Another analogous process is found in toxic pregnancies in which, as in epilepsy, the associated edema reaches its apogee immediately preceding convulsion.

It seems, therefore, if we are really going to make diagnostic studies of our cases of epilepsy, studies that will enable us to determine what is actually the matter, it will be necessary to broaden our usual methods of investigation. The formal neurological examination, by which the actual pathology of the disease has been systematically overlooked for ages may be continued on the ground that it does no harm and may occasionally be useful in detecting important secondary changes. But whatever else is done, the actual examination of the case must embrace, first, the blood with reference to the presence or absence of Bacillus epilepticus, and for the further purpose of determining the blood values; next, the careful x ray examination of the abdominal viscera with reference to determining more particularly the position of the stomach and intestines and the transit of ingesta through them; third, the repeated analyses of the urine and saliva with reference more particularly to the existence and degree of acidosis. I may go a step farther and assert, as I do, that, in the light of evidence now in the hands of the profession, any examination of epileptics that stops short of these features, necessarily stops short of diagnostic accuracy. Every epileptic has the right to know the condition of his intestines and the condition of his blood, and it is the obvious duty of the medical adviser either to give the information or put the patient in the way of obtaining it. This obligation rests with singular force upon institutions in which large numbers of epileptics are held in custody. I am gratified to state that in certain of these institutions, careful investigations are being made along the lines that I have indicated. In every instance in which I have been requested to do so, I have sent to these institutions, public and private, both cultures and slides of the organism, together with literature, and I am gratified to state that, in a number of instances, I have already been favored with confirmatory reports. The following letter from Hinkelmann, which I have permission to cite, is an example:

> I beg to state that I have obtained both the organism and the spores of your Bacillus epilepticus directly in blood smears from a case of epilepsy. I took the blood about three hours after the patient had had a convulsion, and according to my special procedure, the details of which will appear in a coming article of mine. I obtained masses of both the organism and the spores. The spores are identical with those shown in your cuts and very characteristic. When once seen, one will always recognize them again. I am having photographs made from my slide and will add these to my illustrations of my coming article on the dissemination of bacteria in the blood. . . .
>
> I am fully convinced now that your organism is the cause of the seizures of epileptics. My finding it in an isolated case so far distant from the source of first investigation adds much to the proof. I also made cultures which show the motile organisms present. I note they are especially active and have a still higher motility than typhoid bacilli.

As every investigator, of whom or of whose work I have knowledge, contemplates publication of his findings, I naturally desist from mention of names or institutions. The same motive obtains, for even more obvious reasons, in the instance of institutions of another type, from whose medical officers I have received letters, from some of which I quote. One says: "Your work impresses me most favorably, but unfortunately we have neither an x ray outfit nor a hematological service and cannot take up the investigation." Another writes: "Your conclusions are logical and I would like to comply with your request to investigate the question of the infectious nature of epilepsy in at least some of the fourteen hundred inmates that we have here, but I am sorry to say that we have no equipment with which to do it." Still another complains: "I have been trying ever since I came here to get the outfit to do the very work that you have done, but my B-o-r-e-d won't budge in the matter."

In another instance I found that the several hundred epileptics in an institution were being made the subject of "research," but on inquiry I ascertained that there was neither an x ray plant nor a hematological service in the place, that no x ray picture had ever been taken, that no blood examination had ever been made, and that all the "research" had been psychological in character!

I do not wish to be understood as objecting to any possible research that may throw the slightest light upon what has been a baffling problem through the ages. I am not asking that any rational course of investigation with reference to the nature and cause of epilepsy shall be abandoned, at least until its possibilities have been exhausted. I do, however, urge that careful and unprejudiced investigation shall be made along these newer and, I believe, more promising lines. I do this the more insistently in view of the fact that these diagnostic and etiological studies can be made without hazard to the thousands of patients now aggregated in our increasingly populous institutions.

UNION CENTRAL BUILDING.

REED'S BACILLUS OF EPILEPSY.

BY A. J. HINKELMANN, M. D.,
Galesburg, Ill.,
Director, Galesburg Laboratory.

Through the work of Reed,[1] the question of a specific organism as the exciting cause of the seizures of epilepsy has been most ably set forth. Having previously worked from a different basis with an organism I believe to be the same as that isolated by Reed, and having since the appearance of his articles, succeeded in finding the organism in the blood of an isolated case of epilepsy, I am in a position to add a few facts to what Reed has already said. I am sure they will be of further aid to the profession in the direction of reaching final conclusions as to the significance of the organism.

[1] Charles A. L. Reed, *Journal A. M. A.*, January 29 and May 20, 1916.

Method of invasion of the human system. Under this head, Reed has made very clear the point that the organism is evidently taken into the intestinal tract by way of the mouth, and enters the blood through a cecal or an appendicular focus and leaves the question open as to the danger of communication. What would be the consequence in case the organism was ingested by a normal individual, and to what extent may those with predisposing lesions expect to escape infection?

On the basis of experiments I conducted during the summer of 1913, and before I had any knowledge of the pathology of the organism, it may be stated that it is a very frequent inhabitant of the intestinal tract of probably the majority of people. My conclusions at the time of my experiments were that it is one of the regular members of the so called intestinal bacteria.

My interest in the organism was its high resistance to germicidal agents, and through this fact it

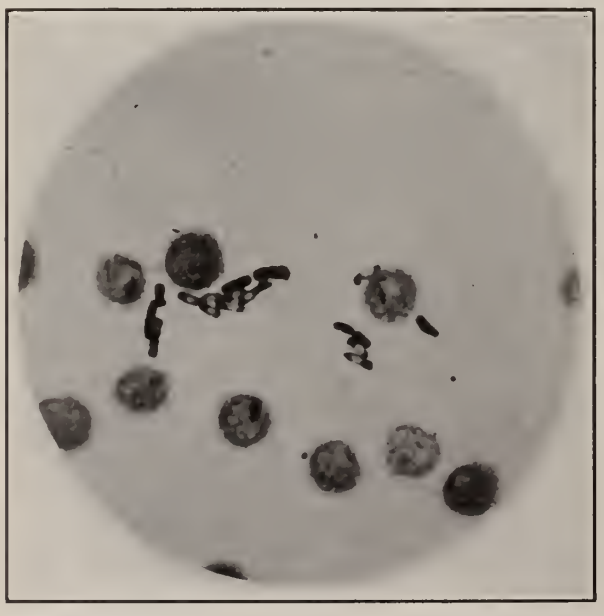

Fig. – Bacillus epilepticus taken directly in blood smears from an epileptic patient five hours after a convulsion.

becomes an easy matter to demonstrate its presence in the intestinal flora and also that it is commonly present. It will live in phenol solutions of from five to ten per cent. for many hours, and a much higher strength is necessary to kill it instantly. Among the very large number of different bacteria that are usually found in the intestines, it is commonly the only one that will survive a thorough treatment of the stool with a five or ten per cent. phenol solution.

My method of isolation was as follows: From twenty-five to thirty grams of solid feces were made into an emulsion with fifty c. c. of a five per cent. solution of phenol and allowed to stand for thirty minutes or an hour; cultures were made on agar slants and incubated. I have never made such cultures from the stools of epileptics with the view of noting how numerously the organism is present, but in normal individuals a loopful of the emulsion spread over an agar slant will yield from one to six colonies after twenty-four hours of incubation.

The organism is highly hemolytic, and to this fact may be due a part of the pathological conditions present in epileptics. Cultures made on blood agar plates will show a hemolytic spot at the point of a growing colony long before the colony itself becomes visible. In the case that came under my observation, I found it abundantly present in the capillaries, and both the spores and the organism could easily be demonstrated in smears from the blood directly.

CONCLUSION.

In view of the fact that the organism does enter the circulation and there multiplies into great numbers and is so generally found in the blood of epileptics, the conclusions of Reed as to its specific nature become at least very plausible. It would be hard to conceive that an organism with such a high hemolytic property could enter the circulation and multiply to such numbers as smear preparations from the blood indicate without producing diseased conditions within, and resulting in corresponding clinical manifestations without.

At any rate, what has already been established in regard to the organism makes the question worthy of serious consideration and extensive investigation. The universal presence of the organism in the intestinal flora is no argument against its probable pathology, but simply adds to the importance of the gateway through which it enters the bloodstream, in considering the treatment.

If further investigation finally establishes that Bacillus epilepticus is the exciting cause of the seizures of this disease, little probably can be hoped for in the way of prophylaxis or cure through efforts to prevent the organism from entering the intestinal tract or to eradicate it when present. Our best attention probably will have to be directed toward lesions which open the way for it from the intestines into the circulation.

THE PATHOGENESIS AND TREATMENT OF EPILEPSY.

A Preliminary Report,

By Henry A. Cotton, M. D.,
Philadelphia,
E. P. Corson-White, M. D.,
Philadelphia,
And W. W. Stevenson, M. D.,
Trenton, N. J.

(From the Laboratory of the New Jersey State Hospital, Trenton, N. J.)

Recent investigations in the field of epilepsy have shown a tendency to depart from the old fatalistic hereditary congenital hypothesis, which was largely a matter of speculation and deduction, to theories based on firmer pathological foundations. Thom (1) has shown a direct heredity in 126 cases of epilepsy out of 157 cases investigated, that is, the parents or grandparents had epilepsy.

It must be emphasized in considering epilepsy that it is probably not a unit or distinct homogeneous disease process, but rather a symptom of several pathological conditions. Among the more recent investi-

gations in this field is the work of Reed (2), whose conclusions were that, 1, epilepsy is an infection; 2, the infecting organism finds its way under circumstances of forced absorption from the alimentary canal into the blood; 3, the conditions that enforce absorption from the alimentary canal consist in mechanical distortions with resulting constipation in the form of either obvious or masked stasis. His treatment consisted in the removal of the anatomical abnormality of the colon, thereby relieving the obstructive angulation of the duodenum where the specific toxin or poison was elaborated, restoring the normal drainage of the bowel. Overeating and constipation have long been recognized factors in the production of the convulsions. There is probably an intestinal stasis and an accompanying absorption of toxic products in many epilepsies, which may of itself be a cause of the convulsions; or the toxicity may be due to some deeper seated cause.

Another view lately brought forward is that disturbance of the pituitary gland may be the cause of the convulsions. McKenna, Johnston, and Heminger (3) have recently studied the skulls of epileptics and out of 115 cases found bony changes in the region of the sella turcica in eighty per cent., while in nonepileptics bony changes were found in only ten per cent. In some case, pituitary enlargements or tumors, some thickening of the clinoid process, and thickening of the bone of the anterior fossa were observed.

We deal here with certain facts which have developed as a result of the work with the Abderhalden reaction in the laboratory of the State Hospital at Trenton. In an investigation of sixty-nine cases of epilepsy, the patients ranging from fifteen to forty years of age, we found that a large percentage gave a positive reaction to suprarenal gland, but were negative to other glands tested; i. e., pituitary, thymus, thyroid, pancreas, testes, and ovary, with one exception—a case lying in status epilepticus that gave a positive reaction to pituitary. Out of twenty-seven cases of epilepsy in this hospital, the blood serum was positive to suprarenal in twenty-four, and one to pituitary as has been mentioned. In the other three cases, the Abderhalden reaction was absolutely negative for all glands. These cases when analyzed were found to be as follows: One infantile paralysis with hemiplegia, one traumatic case, one alcoholic epileptic. The remaining forty-two cases were from sources outside of the hospital, all were tested, and all were positive to suprarenal.

It is significant also that in over 200 cases examined by this method and which included dementia præcox, manic depressive insanity, alcoholic insanity, general paralysis, and senile dementia, all except the so called idiopathic epileptics gave a negative reaction to suprarenal. So we have to admit that at last we have obtained a constant reaction of the suprarenal glands practically limited to epilepsy. Also that the other groups investigated were negative to adrenal. This finding was somewhat of a surprise, as we were investigating primarily dementia præcox and manic depressive insanity. But in several obscure cases, seen in consultation, with convulsions coming in the adolescent or adult life, an Abderhalden test was made to see if it would throw any light on the subject. As these cases apparently were the result of severe fright some months before the onset of the convulsions, this finding was significant, but it prompted us to examine all our patients suffering from epilepsy, with the foregoing result.

In order to study further the relation of this gland to epilepsy, it is necessary to understand some of the physiological activities of the suprarenal. Cannon (4), in his excellent work, has devoted considerable space to the adrenal gland and has given us a solution of this perplexing problem. It could not be said that an excess merely of the suprarenal extract would cause the convulsions, as it has not been proved that such is the case. But Cannon has proved conclusively that one of the principal physiological actions of the suprarenal is the inhibition of smooth muscle fibres such as are found in the intestines. It also relaxes the smooth muscles of the bronchioles and alters the distribution of the blood, driving it from the abdominal viscera into the heart, lungs, central nervous system, and limbs. And Cannon also states that it renders more rapid the coagulation of the blood. This latter phenomenon has been noted in epilepsy and some writers have given the rapid coagulation of the blood as a cause of epilepsy, notably Turner (5) and others. Adrenaline also raises the blood pressure, another physical sign almost constant in epileptics.

Cannon demonstrated not only that great fear produced an excessive secretion of the suprarenal gland, but he made known the fact that the smooth muscle of the intestine was extremely sensitive to adrenaline and became inhibited when it was present in the blood in the dilution of one in 200 million. Thus, we can readily conclude, from the physiological viewpoint at least, that excessive suprarenal secretion would have a very deleterious effect upon the intestinal peristalsis by directly inhibiting the smooth muscles. Hence, the relation between excessive suprarenal secretion, intestinal stasis, and the accompanying absorption of toxic products, as the result of this stasis, can be readily conceived.

We assume then that excessive adrenaline secretion or hyperactivity of the adrenal glands, as shown by positive Abderhalden tests, stands in a causal relation to epilepsy. At present we do not know what the Abderhalden means, so we must explain any reaction by the results found in experiments upon animals. Such experiments with animals reported by Corson-White and Ludlum have shown that this Abderhalden suprarenal reaction does occur after removal of the pituitary and experimental removal of the external function of the pancreas.

1. Dogs in which the pituitary gland has been extirpated soon show definite changes in other glands, first an atrophy of the testicles, and later a slight hypertrophy of the suprarenals, with a positive Abderhalden reaction to suprarenal. This phenomenon has been demonstrated in a number of animals. This relation of the pituitary to the suprarenal gland may account for that type of epilepsy due to a dysfunction of the pituitary gland through trauma or disease of the pituitary gland.

2. Experimental removal of the external function of the pancreas also produces a suprarenal gland reaction.

3. In two dogs irritation of the duodenum by scarifying the external surface, gave a doubtful reaction to suprarenal. This phenomenon may have some bearing upon the fact that inflammatory conditions of the duodenum or a toxic condition due to disturbances of the anatomical relations, such as obstructive angulations, etc., may act upon the suprarenal glands, causing an excessive secretion which in time would further interfere with the intestinal peristalsis, causing more absorption of the toxic products.

The last to be considered is the psychogenic factor, fright. We have undoubtedly cases in our series to which the whole condition could be attributed alone to fright. In these cases the convulsions did not appear until late in life, in one case eighteen years and another twenty-one years, and the convulsions were usually of a mild character, especially in one case occurring almost always at night, only occasionally during the day, and following extra eating at parties, etc. In all these cases the patient never had any previous convulsions, there was no evidence of heredity, and the convulsions could not be attributed to any other cause.

These four conditions which would apparently affect the suprarenal gland are all that we are able to demonstrate at present, but there may be other pathological causes for such overaction of the adrenals. We are of the opinion, however, that these are sufficient to cover a majority of the cases of epilepsy in our series.

TREATMENT.

From the fact that both pituitary gland and pancreas inhibit the activity of the suprarenal gland, it would naturally follow that either one or both glands could be used therapeutically to accomplish this purpose. At first we used the pituitary gland, both the anterior lobe and whole gland, but our results were unsatisfactory. In some of the cases the convulsions increased and in others no effect was noticed.

Then the extract of pancreas was used, half grain tablets three times a day. In this we were much more successful, and many patients while taking the pancreatin did not have convulsions. But in some when the gland was stopped the convulsions returned. In others no convulsions have occurred after discontinuing the gland. The time of the treatment of our cases is too short for us to make any positive statements regarding cures. We can only say that administration of pancreatin has had a decided effect in stopping the convulsions. Nor do we assert that this treatment will alone suffice. It is highly probable that it should be supplemented by surgical procedures in conditions of the intestines indicated by the x ray after a thorough use of the pancreatin has failed. The action of the pancreas in stopping the convulsions can be explained in several ways. In the first place it has a definite effect upon the suprarenal gland, inhibiting its activities. It is also an aid to digestion, and by this function the contents of the duodenum are more quickly digested and the proteins are more rapidly broken down to less toxic products. As in other pathological conditions, the duration of the disease has a distinct influence on the prognosis. It is not to be expected that in an old epileptic of years' duration, where pronounced dementia has supervened, any curative effect will be produced by any treatment. And it must be further borne in mind that it is essential to differentiate the type of case to be treated. In epilepsy, which is due to syphilis, alcohol, trauma (certain types) associated with infantile paralysis, idiocy, etc., we can offer little hope from this method, especially as these cases exhibit a negative reaction to suprarenal.

Unfortunately we have not had time to study our cases by means of the x ray. Both skull and abdominal examinations should be made and existing abnormalities corrected. A complete study of the metabolism should also be made further to confirm the facts here presented. We hope to supplement this preliminary report by a further communication embodying such studies as we have outlined.

CONCLUSION.

From the facts deduced by others and presented in this paper we conclude that:

1. At least one type of epilepsy is probably a disease process dependent upon absorption of toxic or poisonous products from the intestinal canal.

2. This stasis may be produced by an overaction of the suprarenal gland.

3. Hyperactivity of the adrenal gland may be caused by, a, dysfunction of pituitary, b, dysfunction of pancreas, c, irritation of duodenum, d, severe fright or emotional disturbance.

4. Treatment by administration of pancreatin should be employed in preference to surgical procedures.

5. Surgical procedures should be employed in long standing cases where other treatment fails.

TOXIC MANIFESTATIONS OF EPILEPSY AND THEIR RATIONAL TREATMENT.

By Ralph H. Spangler, M. D.,
Philadelphia.

Post mortem examinations have revealed no definite pathogenesis for the so called idiopathic or essential epilepsies. The primary or exciting cause has never been determined. The organic epilepsies, such as those arising from traumatic lesions of the skull, brain, or its membranes, and those which are associated with focal organic disease of the brain, such as tumor or thrombosis, may be explained by direct irritation of the motor cortex. But how to account for the more subtle attacks or those diagnosed as genuine epilepsy, is a more difficult problem, unless the indefinite theory of inherent irritability of the cortical cells is accepted as an explanation.

From time to time it has been contended by certain investigators that an excitant of epileptic

seizures might be found in toxic or autotoxic causes. To prove this contention it is necessary to demonstrate the formation of poisonous substances in the gastrointestinal tract, and their absorption into the blood, or to find one or more toxins developed by disturbance of general body metabolism.

Since the bloodvessels must ultimately carry any abnormal substance to the brain, to act as an exciting cause of the epileptic attacks, the toxin must at times be in the blood serum or in the corpuscles.

In a paper (1) read before the Pennsylvania State Medical Society, September 25, 1912, I cited some well known facts of common observation to physicians who had under their care many cases of epilepsy. Attention was called to the fact that epileptics in whom develops an acute fever or an infectious disease, as a rule show no epileptic symptoms

FIG. 1.—Illustrating position of stomach and colon in a case of epilepsy, when patient is lying down. (Plate by M. F. Percival.)

during the intercurrent disease; the same subsidence of the epileptic convulsions and border line symptoms with their concomitant manifestations is often observed in cases of pregnancy. Again, operations performed for reasons that have no bearing on the epileptic condition, or with which there is associated much loss of blood, nearly always cause a temporary suspension of all epileptic symptoms. It was suggested that these conditions might be explained by the fact that through a demonstrable alteration of blood conditions, associated with a lengthened clotting time, the accumulation, so to speak, of substances in the blood, which may possibly act as an etiological factor of the epileptic attack, are prevented from forming in sufficient quantities to induce seizure. Or, perchance, incompatible poisons of an intercurrent disease may counteract the toxin which ordinarily accumulates in an epileptic and excites the seizure.

It was suggested that the blood of an epileptic may contain what might be called an epileptic toxin, which toxin accumulates more and more from time to time, until a certain intensity is reached with shortened coagulability of the blood, and an explosion (the epileptic attack), as it were, takes place. The question whether the hemogenetic change was due to an autointoxication I felt needed further careful investigation.

ANIMAL EXPERIMENTS.

Krainsky (2) found that the subcutaneous injection of blood taken from an epileptic patient just before a single attack or from patients in status epilepticus, caused the death of an animal in four or five days. Injection of the blood during the interparoxysmal periods gave no such results. He concluded from his experiments that the blood of epileptics contained a poison which gave rise to recurring convulsions. He said that the poison was the carbamate of ammonium. He stated that the injection of ammonium carbamate into animals produced symptoms comparable to those induced by the injection of the blood of epileptics. In a further series of experiments, Krainsky found carbamic acid present in the blood of epileptics. He then treated epileptics with lithium carbonate, and found it temporarily beneficial.

Extensive studies of the urine of epileptics have been made in search of a toxic cause for epilepsy. No constant connection has been found to exist between variations in the amount of urea, uric acid, chlorides, indican, or the presence of sugar, albumin, or peptone, and the occurrence of epileptic seizures.

The injection of the urine of epileptics into animals, done originally by Bouchard (3) in 1885 and later by Voisin and Peron (4), produced toxic symptoms, but Bouchard, in 1894, and Roncowin (5) both found that normal urine injected into animals produced symptoms of toxemia.

Bra (6), in 1902, described a parasite found in the blood of epileptics. He has found it in fresh blood at or near the time of an attack; he cultivated it in ordinary medium; it was reproduced when injected into the blood of rabbits; and finally the rabbits thus treated had convulsions. Out of 100 patients examined he isolated the microorganism in seventy. Rabbits inoculated with his organism died in clonic convulsions. The number of "neurococci," as he calls them, increased with an impending attack and diminished again afterward, until none could be found during interparoxysmal periods.

Reed (7) has recently (1916) described an organism similar to Bra's and calls it Bacillus epilepticus. He confirms Bra's findings, thinks the principle of immunization should hold good in these cases, and is investigating the possibilities of a vaccine. To the best of my knowledge, at this writing, laboratory investigators have not corroborated these findings.

With a view of ascertaining the degree of toxicity common to epileptics' blood, Boston and Pearce (8) inoculated rabbits with the blood of epileptics and record the following interesting observations:

The blood from a thirty-five year old male epileptic was drawn after the last of four severe seizures in twenty-four hours. Ten m. were injected subcutaneously into a rabbit; four days later, more blood was drawn and twenty mils

injected into the same rabbit, and after another three days' lapse, a third inoculation of twenty mils was made. The count of this rabbit before injection was about normal. The count, seven days after the first injection, four days after second injection, and twenty-four hours after the third, was: Hemoglobin, fifty-five per cent.; red blood cells, 4,680,000; white cells, 5,600. Differential leucocyte count: Polymorphonuclears, fifteen per cent., all showing some eosinophile granules; large lymphocytes, fourteen per cent.; small lymphocytes, twenty-five per cent.; eosinophiles, forty per cent.; myelocytes, six per cent.

A similar experiment was made with another rabbit, using defibrinated blood. The differential count of this rabbit before inoculation was: Polymorphonuclears, four per cent.; with fine eosinophile granules, sixteen per cent.; large lymphocytes, twenty-five per cent.; small lymphocytes, fifteen per cent.; myelocytes, five per cent.; myelocytes with eosinophile granules, one per cent.; eosinophiles, twenty-four per cent. Leucocyte count, 8,000.

Forty-five mils of defibrinated blood was injected from the same patient (who had had no attacks for twenty-three days) into the peritoneal cavity of this second rabbit. Forty-eight hours later, the differential count was as follows: Polymorphonuclears with eosinophile granules, twenty-nine per cent.; large lymphocytes, four per cent.; small lymphocytes, nine per cent.; large mononuclears, three per cent.; eosinophiles, fifty-four per cent.; transitionals, one per cent. Leucocyte count, 17,000.

Fig. 2.—Showing ptosis of stomach and colon in same case when patient is standing. (Plate by M. F. Percival.)

It would seem from experiments with this case that there was a profound toxemia set up in both rabbits, as shown by the definite blood changes seen in the animals.

The blood of a second epileptic patient who was having from one to four major seizures a day was withdrawn, and twenty mils of his defibrinated blood was injected into another rabbit at three day intervals. The hemoglobin in this rabbit before first injection was fifty per cent. and it gradually rose until after the second or last injection it was sixty-six per cent. The leucocytes were 9,000 before inoculation; 14,000, twenty-four hours after first injection, and fluctuated between 18,000 and 10,000 until the sixth day after the last injection. The red corpuscles fell from 6,000,000 to 2,856,000 twelve days after the first injection. The eosinophiles rose from one to fifty per cent. after the second injection. The polymorphonuclear cells fell from thirty-seven to three per cent. within twenty-four hours after last injection, and rose to eighteen per cent. six days later.

The tendency to widespread alteration in the proportional relation of the blood cells and the marked increase in the leucocytes point toward toxemia as a probable factor in this disease. It is interesting that these changes are in striking contrast to those noted in the leucocytosis of an ordinary septic process, where the polynuclear cells show a decided increase. After each inoculation Boston and Pearce found that an eosinophilia developed similar to that observed in the blood of patients suffering from a parasitic disease. This appears to suggest a possible relation between epilepsy and parasitic infection

As control tests Boston and Pearce injected the blood of two healthy students into the peritoneal cavities of two healthy rabbits. The blood of these rabbits was examined daily for a week and no alteration was found in the hemoglobin, the red cells, or the leucocytes.

In discussing my paper of September 25, 1912, above referred to, Dr. L. N. Boston cited the following circumstance: He injected twenty c. c. of defibrinated blood from a case, not known at the time to be idiopathic epilepsy, into the vein of an anemic patient. Seven days later, the patient had two epileptic seizures. These were followed by one to three attacks daily for a period of four or five days, when the patient died of exhaustion. Boston reports that a similar inoculation was performed in another case of anemia by Dr. F. P. Henry (9) and the patient acquired true epilepsy.

With the foregoing observations and interesting facts in mind I have continued to investigate the toxic manifestations of epilepsy for the past four years, and have had the opportunity of examining and studying over 300 cases in private practice. Careful and systematic clinical records have been kept, and many laboratory examinations, with accurate data, have been recorded.

Occasion is taken at this time to report my further personal clinical observations, some of which have been already cited by other investigators, and to record certain laboratory findings for the purpose of correlating more definitely the recognized toxic manifestations of the so called idiopathic epilepsies.

CLINICAL OBSERVATIONS.

The temperature was recorded twice daily in ninety epileptic patients in my private sanatorium over periods of time ranging from one month to three years. In eighty per cent. of these cases the temperature range was uniformly subnormal. At times it was as low as 96° F. and during interparoxysmal periods usually ranged between 97° and 98° F. Within twenty-four hours of an attack the temperature frequently rose to between 98° and 99° F., and following an attack at times it would touch 99° or even 100° F. A fluctuating, subnormal temperature is almost a constant characteristic symptom of epilepsy.

The pulse rate in epilepsy, as in many conditions associated with nervous symptoms, exhibits many oscillating phenomena. In my early observations of epileptics I frequently noted that the pulse rate was abnormally slow. In some cases there is regularly slowing of the pulse rate for from twelve to twenty-four hours before a seizure. The pulse rate of all my sanatorium patients is taken night and morning and a review of these records shows a

tendency to a slow pulse rate, ranging from forty-four to sixty-four beats a minute in sixty-five per cent. of the cases. During the attack and for some time (varying from a few to twenty-four hours) after an attack, the pulse is accelerated, but in many instances the slow pulse rate is present until the actual convulsion occurs.

The blood pressure of over 300 epileptic patients has been taken, and a review of case records shows that in the cases unassociated with organic conditions it has ranged from ten to thirty points below what is considered the normal average for the age of the patient. A systematic investigation in ten cases is appended in the following table:

						Systolic			Diastolic			Pulse Pressure		
Case No.	Sex.	Age.	No. of tests.	Normal (Faught).	Average.	High.	Low.	Average.	High.	Low.	Average.	High.	Low.

*Faught subtracts 10 mm. in female patients when computing normal averages.

CLOTTING TIME OF THE BLOOD.

For three and a half years the writer has studied carefully the clotting time of the blood in each case of epilepsy that he has had the privilege of examining. A review of the case records shows that more than 9,000 clotting time tests have been made on 380 cases. A Boggs coagulometer was used in making all the tests, and in order to eliminate variation in personal equation and have as nearly uniform results as possible, the writer made all of these estimations.

In a previous series of cases (10) reported the average clotting time was 3.04 minutes. The longest clotting time in this series was four minutes; the shortest 1.5 minute. In the present series of 100 cases the average clotting time was 3.14 minutes. The longest clotting time in this series was six minutes, the shortest 1.5 minute. The tests referred to in these two series were all taken during the interparoxysmal periods and before treatment was instituted. Dr. John Turner (11) has shown that the clotting time of the blood is quickened just before and during the period that a patient is having attacks.

The normal average clotting time of the blood with the Boggs instrument is given by Hinman and Sladen (Boston and Anders, *Diagnosis*) as being five minutes and six seconds. It is generally admitted, however, that under normal conditions comparatively wide variations in the clotting time of the blood may be found in the normally healthy subject, when any of the established methods for determining the same are employed. Some workers with the Boggs instrument have made the normal limit between three and eight minutes (Simon, *Clinical Diagnosis*, 7th edition). It has been conclusively proved to the writer's mind that most cases of so called essential epilepsy show the phenomena of shortened clotting time of their blood. The fact that this time in some cases falls within the limit of what may be regarded as normal, say three to eight minutes with the Boggs instrument, does not prove that the epileptic's clotting time is perfectly normal and not abnormally short.

The clotting times in this series of 100 cases were divided as follows: Seven fell between one and two minutes, forty-five between two and three minutes, thirty-three between three and four minutes, thirteen between four and five minutes, and two between five and six minutes.

These findings indicate that, in this series of 100 cases, in only two per cent. of the cases did the clotting time, during interparoxysmal periods, exceed the normal average of five minutes and six seconds. In ninety-eight per cent. of the cases it was below the normal average, and in fifty-two per cent. of the cases it fell below the shortest limit of what may be considered the normal range (three to eight minutes).

ALKALINITY OF THE BLOOD.

The alkalinity of the blood was tested in a series of twenty-one epileptic patients and in three control cases. These patients and control cases were all on the same diet, which was a general mixed one, consisting essentially of fruits, cereals, green vegetables, eggs, and milk, with meat only once daily. The patients included fourteen males and seven females. The control cases were all male.

There was a total of 314 tests made. The blood was taken daily between 10 and 11 a. m. in each case, and in five of the patients and two of the control cases the tests were also made between seven and eight p. m. A general summary of the results is tabulated below:

PATIENTS.

Case number.	Lowest.	Highest.	Average.
1	159	212	171
2	133	184	163
3	212	239	196
4	140	239	174
5	140	212	167
6	186	239	213
7	180	212	196
8	133	212	174
9	140	266	176
10	133	176	159
11	176	239	212
12	140	212	176
13	176	266	196
14	156	212	185
15	159	159	159
16	184	196	188
17	140	212	159
18	159	176	167
19	212	212	212
20	218	218	218
21	176	256	239

CONTROL CASES.

Case	Lowest.	Highest.	Average.
1	176	266	214
2	176	239	204
3	218	218	218

General average for the 21 patients, 186.
General average for the 3 control cases, 212.
The Dare hemalkalinometer was used in making the tests. According to the Dare method, 20 c.mm. of normal blood is neutralized by two c. c. of reagent or 266 mgm. of sodium hydrate to 100 c. c. of blood. Therefore, the 266 point line is considered as normal in the tabulated chart.

It will be noted with the diet used that the control cases averaged 212 or fifty-four points below the normal average, while the patients averaged only 186 or eighty points below the normal and twenty-six below the control cases. Only twice in all the tests did the alkalinity of a patient's blood reach the normal point of 266.

In comparing the alkalinity of a patient's blood at the time of an attack with the alkalinity at times when no seizures occurred, it was found that while the general alkalinity in interparoxysmal periods was lower than the average as established by Dare, and also lower than the control cases by twenty-six points; nevertheless, on days when seizures occurred it was found that the alkalinity of the blood was not appreciably influenced by the attack itself. It was observed, however, in a patient or a control to whom hypodermic injections of crotalin were given, that the alkalinity of the blood was increased from fifty-three to eighty points within twenty-four to forty-eight hours after the injection.

GASTROINTESTINAL MANIFESTATIONS.

A coated tongue, fetid breath, gastric disturbance with its various manifestations, intestinal flatulence, and constipation with its associated evidence of so called autointoxication, are almost constant symptoms in epilepsy. In some cases stasis of the intestinal current resulting from ptosis or twists along the course of the primæ viæ as revealed by the x ray (Figs. 1 and 2), cause pronounced absorptive intoxication as emphasized recently by Reed.

The foregoing clinical observations, including a fluctuating subnormal temperature, slow pulse, low blood pressure, shortened clotting time, and lowered alkalinity of the blood, together with constipation and its associated manifestations, are generally recognized evidences of a low grade infection or toxemia. In addition to calling attention to these commonly observed toxic manifestations in epilepsy, I wish to record some definite data from a detailed study of blood examinations in relation to epileptic phenomena.

BLOOD COUNTS IN 100 CASES OF EPILEPSY.

I studied the blood in a series of 100 cases of epilepsy before treatment was started. These patients came from thirty-six different States, none of them were institutional, all were from well to do families, so that locality, climate, lack of nutrition, etc., may be eliminated when considering the blood conditions. The series comprised thirty-nine females, whose ages ranged between ten to sixty years, and sixty-one males, whose ages ranged between three to sixty-five years.

The hemoglobin was estimated, a red and white count taken in each case, and 2,204 differential leucocyte counts were made. The hemoglobin in this series averaged eighty-four per cent.; the red cells averaged 4,640,037, and there was only occasionally evidence of degeneration. The white cells ranged between 3,650 and 9,360 during interparoxysmal periods. Shortly after attacks they varied from 8,000 to 37,500. As a general rule, my experience would indicate that an epileptic attack is almost invariably followed by a tendency to leucocytosis (12).

DIFFERENTIAL LEUCOCYTE COUNTS.

A study and analysis of the differential leucocyte counts in this series of 100 cases of epilepsy is most interesting. The following table summarizes my findings:

Cell	Normal Range (Howell.) Percentage.	Range in 100 Cases of Epilepsy, (Spangler.) Within Normal limit.	Above normal limit.	Below normal limit.	Average for the 100 cases in the present series.
Small Lymph	20-25	39 per cent.	51 per cent.	10 per cent.	27.11 per cent.
Large Lymph	1 or less	2 per cent.	98 per cent.	.....	9.31 per cent.
Polymorphonuclear	60-75	59 per cent.	3 per cent.	38 per cent.	60.1 per cent.
Eosinophiles	4 or under	88 per cent.	4 per cent.	8 per cent. absent	2.19 per cent.
Transitionals	2-10	13 per cent.	.....	87 per cent.	0.78 per cent.
Basophiles	1 or less	31 per cent.	26 per cent.	43 per cent.	0.51 per cent.

FUNCTION OF EOSINOPHILE CELLS IN EPILEPSY.

In going over the 2,204 differential leucocyte counts in this series of 100 cases, rarely was there found an increase in the percentage of eosinophile cells above the normal (four or five per cent.), either before or after an attack. Occasionally there was recorded a six or eight per cent. of eosinophile cells after a seizure, but it was the rule to find no such evidence of eosinophilia.

In contrast to these findings, the experience of Boston and Pearce (see above), who found, beside a general leucocytosis, an increase of from twenty-four to fifty per cent. in the eosinophile cells of rabbits after they injected the animal with blood from epileptics, is most significant, especially since no actual convulsions were produced in the animals thus inoculated.

Foster (13) has shown that the virus of diphtheria produced an eosinophilia when inoculated experimentally into animals. He concludes that the function of the eosinophile in diphtheria is to antagonize the toxins of the disease. He also found that eosinophilia produced in guineapigs was phagocytic for the diphtheria bacillus.

The foregoing facts and experiences seem to indicate that while in an epileptic patient there is often produced, at the time of an attack, a *general leucocytosis,* preceded by or associated with other toxic manifestations (irregular subnormal temperature, slow pulse, low systolic blood pressure, decreased alkalinity, and shortened clotting time of the blood), there *is not* present an eosinophilic leucocytosis such as is produced in an animal by the injection of the toxic blood from an epileptic patient.

Is it not possible, therefore, that this inability on the part of an epileptic patient to produce an eosinophilia (negative chemotaxis), when his system is surcharged with toxin, may account for the occurrence of the attack? In other words, if a patient in whom there has accumulated enough toxin to produce an attack, could acquire an eosinophilic leucocytosis of sufficient proportions to counteract the toxin (i. e., become positively chemotactic to eosinophile cells), the possibility of an attack occurring would be greatly lessened; or if an eosinophilia can be produced in a patient, is it not possible (by the formation of antibodies or the phagocytic action of the eosinophile cells) to neutralize the toxin and avoid the attack?

TREATMENT.

A rational therapy for epilepsy, based on the toxic manifestations detailed above, which has proved of value in the writer's experience, includes a mixed easily digested diet, systematic exercise, and free evacuation of the bowels. Sulphate of magnesium often acts best, but in certain cases of stasis with malposition (ptosis or twists) of a part of the intestinal tract, operative correction, as advocated by Reed, may be necessary. At times, the use of salol, oxgall, or lactic bacillary tablets, according to the individual indications of the case, are of value. In some cases an antacid or bitter tonic is serviceable, and in others diaphoretic and diuretic medication is of much help. In short, a common sense eliminative and corrective therapy must be instituted to combat the toxic manifestations as evidenced in the particular case.

The tendency to shortened clotting time of the blood, so uniformly present in many of the cases of epilepsy which it has been my privilege to treat, is best overcome with properly regulated doses of crotalin administered hypodermically. Crotalin also tends to increase the alkalinity of the blood, which is usually low in cases of epilepsy. Moreover, crotalin will produce an eosinophilia (14), a condition which, as I have shown in this paper, seems to be desirable for the purpose of counteracting the toxin which is present in the blood of epileptic patients. In fact, the patients who have responded most satisfactorily to treatment in my hands are those in whom properly regulated doses of crotalin have produced an eight to twelve or fifteen per cent. eosinophilia, and in whom a clotting time (Boggs instrument) of six minutes or over is maintained. The following case reports well illustrate these facts:

Case I. Male, aged twenty-four years. Parents, two brothers, and two sisters living and well; grandfathers on both sides were alcoholic and suffered from paresis. Patient was fourth in order of birth, full term child, and development was normal. Whooping cough the only illness of childhood. At eighteen years of age had grippe, and two months later a convulsion. There occurred two attacks the first year; four or five the second year; the third and fourth years, attacks occurred from two weekly to a month apart; the past two years the seizures were at intervals of ten days to a month and a few times had two attacks in twenty-four hours. His attacks were all of the major form with no definite aura, but with a typical cry, tonic and clonic convulsion, biting of the tongue, occasional incontinence of urine; frequently the left shoulder would be dislocated during the attack.

He had been taking 150 grains of bromide daily when he came under my care. This patient was under my immediate care from July 7, 1913, to September 8, 1915. Bromide was gradually reduced, and at the end of two months entirely withdrawn. Crotalin solution by hypodermic injection was started and continued at from five to seven day intervals. Fel bovis, salol, and pituitary extract were administered at various times and the bowels kept regulated with Epsom salts.

During the first eight months of crotalin treatment fifteen major attacks occurred. Twice there were two seizures in one day and the longest interval between attacks was six weeks. The last attack occurred March 2, 1914. Grain 1/150 of crotalin was continued at weekly intervals for one year; then for six months at ten day intervals. It is now a little over two years since any attack has occurred, and it has been six months since any crotalin was administered.

The clotting time of the blood in this case was three minutes fifteen seconds before using crotalin, and during the first year of its administration fluctuated between four minutes fifteen seconds and six minutes fifteen seconds. The clotting time was taken weekly for a year after the attacks stopped, and fluctuated between six minutes and six minutes forty-five seconds—only on one occasion did it drop below six minutes during the year.

A differential leucocyte count was made two days after each crotalin injection, and the percentage of eosinophile cells in these counts ranged from five to sixteen per cent., and their average for the two years and two months of continuous treatment was 9.29 per cent.

Case II. Man, aged twenty-five years. Referred by Dr. William R. Barron, of Columbia, S. C. Diagnosis, major and minor epilepsy. Parents living and well. Parental grandfather had epilepsy. Father was alcoholic and subject to migraine. Oldest child, full term, normal birth, no spasms during childhood. Measles and mumps as a boy. "Fainting spells" began at twelve years and continued from one to two months apart until sixteen years of age, when typical convulsions began to occur and a diagnosis of epilepsy was made and bromide treatment started. Bromide and sedative treatment was continued for seven years, and the last year there occurred (March, 1913, to March, 1914) eleven major convulsions. The longest interval between attacks during this year was seven weeks.

The patient was under my immediate care from April 15, 1914, to September 11, 1914. Crotalin in doses ranging from grain 1/200 to grain 1/100 was administered at from five to eight day intervals, and a capsule containing fel bovis, salol, and phenolphthalein was used to regulate the bowels. One attack occurred May 30, 1914, during the five months he was under my personal care. Then he returned home and the crotalin injections were continued by Doctor Barron and he was free from attacks until May 20, 1915 (ten days less than a year). This was the last attack he had had at this writing and it is now five months since crotalin injections were discontinued.

The clotting time of the blood in this case was four minutes thirty seconds before starting crotalin and fluctuated between five minutes and six minutes thirty seconds during the five months he was under my observation. A differential leucocyte count was made two days after each crotalin injection, and the percentage of eosinophile cells ranged from six to thirteen per cent. and averaged for the five months 10.1 per cent.

Case III. Man, aged thirty-two years; father died at sixty-six years of nephritis; mother living and well; one brother and a sister living and well. Family history negative as to epilepsy, insanity, and alcoholism. Patient second in order of birth, full term, noninstrumental delivery; no spasms in infancy. Diphtheria at six years and soon after began to have petit mal seizures. First major attack at fourteen years. He has had major attacks from one to three months apart for last ten years. During this time has rarely gone a week without a minor attack, and it was a frequent occurrence to have a series of ten or a dozen lapses (petit mal) in a day.

The patient has been under my immediate care since March 21, 1914. Crotalin solution varying from grain 1/400 to 1/200 at a dose has been administered at six to eight day intervals. The bowels had been regulated with cascara, oxgall, and phenolphthalein at bedtime and a weekly dose of magnesium sulphate. Lactic bacillary tablets had been used from time to time for intestinal disturbance.

Since the crotalin treatment was started this patient has had one major attack, November 27, 1914. Seventeen months elapsed after this attack occurred and the lighter seizures entirely disappeared.

The clotting time of the blood in this case was three minutes before starting crotalin, and for fifteen months at the weekly tests has ranged between five and a quarter and six and a half minutes. On

only three occasions, however, during this time has it dropped below six minutes.

A differential leucocyte count was made two days after each crotalin injection, and the proportion of eosinophile cells has ranged between four and eighteen per cent. The average proportion of eosinophiles in 106 weekly counts has been 8.2 per cent.

CONCLUSIONS.

1. The attacks, in many of the so called idiopathic cases of epilepsy, are caused by a toxin which is carried in the blood. The exact nature and origin of the toxin is at present undetermined.

2. An accumulation or intensity of this toxin in an epileptic will cause an attack, associated with a general leucocytosis, but *not an eosinophilia.*

3. The blood of an epileptic injected into an animal causes a general leucocytosis with a *marked cosinophilia,* i. e., the epileptic toxin thus inoculated into an *animal* exerts a *positive chemotaxis* for the eosinophile cells.

4. A patient afflicted with epilepsy in most instances does *not* produce, or has lost the power to produce an eosinophilia; the toxin is not antagonized and an attack occurs, i. e., in a patient afflicted with epilepsy the toxin is *negatively chemotactic* for eosinophile cells.

5. The clotting time of the blood is shortened before an epileptic seizure. The range of the clotting time of the blood in eighty-five per cent. of the cases, in the foregoing series of 100 patients, was shorter during interparoxysmal period (1.5 to 4.5 minutes) than it is in normal subjects (three to eight minutes as given by most investigators).

6. The alkalinity of the blood is lower in cases of epilepsy than in control, nonepileptic subjects on the same diet.

7. The writer has demonstrated that the hypodermic injection of crotalin, in properly regulated doses, has produced moderate degrees (eight to fifteen per cent.) of eosinophilia, has lengthened the clotting time, and increased the alkalinity of the blood in certain epileptic patients, thus greatly modifying the character of the seizures and in some cases holding the attacks in abeyance indefinitely.

8. The eosinophilia produced in an epileptic patient by crotalin injections seems to antagonize the epileptic toxin and, possibly by the formation of antibodies, neutralizes the toxin and prevents attacks.

Treatment of Morphinism.—W. C. Ashworth (*Charlotte Medical Journal,* August, 1916) advises the substitution of pantopon for morphine. It can be given hypodermically and internally. The withdrawal of pantopon is attended with less discomfort to the patient than is the case with morphine.

PELVIC INFECTION.*

By A. J. Walscheid, M. D.,
New York,

Adjunct Professor Gynecology, Polyclinic Medical School and Hospital; Consulting Surgeon, F. R. Home, North Bergen, N. J.

Pelvic infection! What a broad term to designate a condition which, if correctly diagnosticated, proves the fallacy of its application! To say that pelvic infection is an infection in the pelvis does not indicate anything and conveys but one conclusion—that the pelvis as a whole has become the seat of bacterial activity. It does not, however, designate what part of the pelvis, or carry with it any pathological or anatomical significance whether we are dealing with endometrial, cul-de-sac, annexal, or parametrial involvement.

It is established that each of these conditions can exist alone, in consequence of, or subsequent to the other. In each and every instance of pelvic inflammation, however, an intelligent and indicative classification can be demonstrated following the incipiency of bacterial invasion; their propagation, the pathological disturbance they create, and the clinical signs.

The term, pelvic infection, therefore, is ambiguous and misleading in its general application. It should be applied only to crown a classification with proper subdivision of those parts especially involved in the infective process. As an example, we know that the gonococcus has a predilection for Bartholin's duct, the urethra, and the cervical canal, and that the internal os acts as a barrier to bacterial migration. We also know that this germ is distinctly a surface rider, but very rarely penetrating beyond the submucous coat and dying if pent up in its own secretion. It destroys tissue which terminates finally in fibrotic change of any and all parts attacked. Its final seat of most serious activity is in the form of salpingitis, and not pelvic infection.

It is not this form of infection which interests us, however, but the puerperal type of bacterial invasion, particularly into that portion of loosely connected cellular tissue situated between the folds of the anterior and posterior peritoneal layers, otherwise known as the broad ligaments, containing the vascular, neurotic, and lymphatic supply to the uterus and annexa. Its topographical determination is made up of certain zones of location within the boundaries of distinct, closer peritoneal infolding, giving them characteristic names according to their locality.

I advise my readers to refresh their memories concerning the elementary anatomy of the pelvic peritoneum, particularly of what is known as the parametrial space.

Now, how do bacteria enter the parametrial space? The protective resistance of pelvic infection depends upon a number of factors: 1. The integrity of the uterine epithelium; 2, the virulence and number of bacteria; 3. the situation and site of entrance and their ability to propagate, and, finally, 4. organic resistance. The severity of the condition depends on the virulence, accentuated by the character and quantity of the bacteria. The site of in-

*Read before the North Hudson Physicians' Club, Weehawken, N. J.

vasion leads to the character of the general disturbance, whether mild or severe. Another point is the question of dealing with a single or mixed infection.

The bacteria enter the genital tract through the uterine canal. They may produce all the symptoms of a severe general infection, and yet the virulence, activity, number of bacteria, etc., are not sufficient to overcome epithelial resistance. Upon the epithelial surface the putrefactive, sapremic disturbance goes on, limited to a septic endometritis or metritis. It produces an intoxication of the general system, but the true bacteria are not conveyed any further, If the phagocytes and other concomitant phenomena of inflammatory reaction are sufficient to confine the infection to the endometrium, a foul smelling discharge, or seropurulent, bacteria-holding leucorrhea presents itself. If the infection enters the uterine wall, a localized, tender, soft, boggy uterus with painless annexa is the only physical sign of the existing metritis. Metritis is always secondary to endometritis, but the latter can exist alone. A high temperature, full, bounding pulse, foul, seropurulent, or bloody discharge, flushed face a few days after labor, exhibit all the signs of toxemic absorption from endometrial parasites unable to break through nature's epithelial and leucocytic defense.

The gonococcus, on the other hand, acts in a different manner. The germs may remain in the arbor vitæ of the cervical canal, passing unnoticed until proper conditions, such as the puerperal or abortive state, bring about a rapidly ascending and virulent infection. Active germicidal propagation and turf-like dissemination of the rapidly growing cultures soon convey the germs to the tubes. Continuity of tissue, leucocytic amebas, and ciliated epithelium play an important part in this conveyance, but the final result is salpingitis in its various forms, with the formation of pelvic peritonitis, or a cul-de-sac abscess. The diseased condition involves the cul-de-sac and pelvic roof only and bears no relation to the subperitoneal layers.

In parametritis we are dealing with a vastly different condition. Before broad ligament disease develops, there first must be injury and secondly bacterial existence. Furthermore, the true bacterium itself must enter the parametrial space. If a staphylococcic or streptococcic infection enters the genital tract, it makes little difference how much damage it does to the uterus if the true germ does not enter into the parametrium; parametritis will never develop. Sapremia will not produce it, toxins will not cause it, and the gonococci will rarely penetrate the submucous coat and enter the cellular tissue of the broad ligaments. Furthermore, the tissues of invasion must be receptive and the soil for propagation favorable. The soft, boggy condition of pregnancy offers an excellent medium for this infection. Retained placenta, lacerated cervix, septic endometritis are but sites of bacterial invasion from which the true germs enter the parametrial space, and the mode of conveyance, or extension of infection, can only be through the muscular wall or contiguous tissue by means of the lymphatics or blood stream.

In this way we distinguish a thrombophlebitic, or lymphangitic type of infection. In the thrombophlebitic we find the formation of dry, brownish black, or reddish yellow thrombus, hard in consistence, the veins of the pampiniform plexus and uterus swollen, clotted, and edematous. As the infection increases, the clots soften and a thick, reddish brown, purulent mass blends with the gradually softening venous wall and surrounding tissue in the form of an exudate or edema (Martin). It is this form which may suddenly develop pulmonary, cerebral, cardiac, or other remote thrombi lodgment, producing characteristic symptoms of the parts invaded, or producing the general metastatic infection called pyemia. Every case of phlegmasia alba dolens bears a close relation to parametritis due to femoral thrombus.

In the lymphatic type the pelvic cellular tissue is diffusely infiltrated, greatly edematous and pustular, with distended yellowish strands, purulent, greasy plugs filling the glands. The lymphatic system accompanying the vessels, the distended vessels, and sacs are mostly found lateral to the uterus along the ovarian and uterine veins radiating toward the infundibular pelvic, or along the base of the broad ligament (Martin). The edema or exudate of parametritis is the response of living tissue to infection. It exists in all conditions and to the gynecologist should be the compass for therapeutic exhibition. It is localized in the parametrium itself and its object is to keep the bacterial activity within bounds, or destroy its virulence.

In every broad ligament inflammation, the first stage is marked by albuminous fluid distending, swelling, and saturating the pelvic cellular tissue and its interstices, to form a gelatinous mass. This is the first physical sign of parametritis appreciable to the touch. With increase of hyperemia in the course of the inflammatory reaction, the edema correspondingly increases. As the virulence is severe, the reaction will be more active and the exudate more extensive.

The second stage of exudate formation is lymph coagulation with fibrin taking the place of the cellular connective tissue, gradually decreasing the albumin and forming a coagulated, fibrinous mass (Veit, Martin). Accompanying this pathological change there is a marked increase of cellular element in the form of binucleated cells arranged in such a way that every space and interstice of the network of fibrin may be filled with them. This is plainly palpated and demonstrated as the "induration of broad ligament exudate," the hardness we feel being the dense cell wall accompanying the fibrin changes. If the virulence of the bacteria overcomes the cellular fibrin deposit, gradual, insidious, and progressive dissolution from within outward takes place in the form of an abscess. Cell destruction and proliferation are continually battling for supremacy. It means either encapsulation with fatty metamorphosis and absorption, a parametrial scar, or breaking through to follow lines of least resistance (Sellheim).

The location of this reaction depends upon the site of bacterial lodgment, which can be in any of the parametrial spaces, but from a general diagnostic standpoint we shall always find that the first physical sign of all broad ligament infection is thicken-

ing along the lateral uterine edge, either at the upper portion or at the base of the broad ligament. From these parts the infection radiates to the parauterine, paravesical, or pararectal space wherever the bacteria find lodgment and inflammatory reaction takes place (Martin). Within these spaces and along the line of least resistance, the disease produces characteristic symptoms. In the paravesical, it manifests itself in bladder irritation, from frequent urination to pain following urination, from cystitis to a sudden flow of pus after rupturing into the bladder; or the edema may spread through the precervical space over to the opposite side and form a bilateral paravesical exudate. This exudate does not always remain localized, but may follow the round ligament course and enter the inguinal canal, the anterior abdominal and subserous cavity, even to the prevesical space.

In the parauterine space containing the ureteral, ovarian and uterine arteries, the exudate may travel along the ureter under the mesosigmoid to the nephritic fossa, break through the diaphragm into the pleural cavity, or, encroaching upon the ureteral conductivity, bring about urinary disturbance. Constrictive or obstructive interference causes kidney stasis, which may lead to uremia. It may also work its way laterally beneath the iliac peritoneum to the anterior abdominal wall.

In the pararectal type, the rectal symptoms are the most pronounced in the form of a tenesmus, or a marked increase in dejections, even to diarrhea. The exudate may be conveyed through the retrocervical space to the other side, or follow the sacrouterine ligaments around the rectum to the lumbar vertebra and, simulating a Pott's disease, point into the groin or gluteal region, even with bone destruction. The obturator and sacrosciatic foramen and anterior crural space have been known to be the line of exudative progress. Following the retrocervical space, the edema may work upward in Douglas's fold, or downward, separating the retrovaginal septum.

The ultimate result of all parametrial infection is either the formation of an abscess, localized, or breaking through the lines of least resistance; fatty metamorphosis with encapsulation and very slow absorption (Burschbeck and Ettinger); or the development of a scar (Freund). In the two latter instances, the effect upon the uterine circulation not only disturbs its equilibrium, but may bring about chronic functional manifestations which finally affect the organ itself in the form of a marked fibrosis. The greater number of menorrhagic symptoms in women are directly traceable to broad ligament involvement during puerperum or abortion. The termination of parametritis is exudative, purulent, or with scar formation and contraction—the first immediately dangerous to life, the second developing into a chronic parametritis and invalidism.

SYMPTOMS.

Acute septic parametritis begins with pain, high temperature, and chilliness or chill. It may occur early or late, even after the patient is doing her housework. Incubation in any disturbed pregnancy arises through an erosion, injury, or normal puerperal involution. Pain is the prominent symptom; although it may be slight, it is always present, and every pain in the lower abdominal quadrant, especially to the side, should be considered seriously. If an exudate is not felt and only slight abdominal and vaginal tenderness with low temperature is found, we must be on our guard. An exudate may exist and not be palpable, but tenderness is always present in the early stages and is situated at the lateral edge of the uterus. We seldom find it at the pelvic wall. It is unilateral in the early stages, but twenty-four hours may mark its rapid progress over to the side. Deep respiration, jars, coughing, or the slightest movement causes pain, and respiration is usually increased. Continued pain, high temperature, and tenderness, with a palpable exudate at the end of twenty-four hours, indicate the extension of infection. Virulence controls rapidity and the entire local picture.

Severe conditions, however, may not show any constitutional effects, whereas mild exudates may create profound septic exhaustion. Vomiting indicates peritonitis; lochial odor means nothing when the infection has reached the broad ligament. Temperature ranges from 100° to 101° F. with septic remission, the pulse balancing from 100 to 120. Sudden rise of temperature, 103° to 104° F., and pulse with increase of pain means extension of exudate or pus formation. We should make frequent vaginal examinations. The harder the exudate, the better the immediate prognosis. The temperature is also safely diagnostic, as it becomes fixed in four to seven days. Reducing slowly to normal means resolution; rising higher, purulent solution. A temperature suddenly falling means rupture, especially if it rises again. In this way, the temperature may rise and fall for some time, depending upon free or obstructed drainage. Pus formation usually occurs in the first two weeks.

In parauterine parametritis, we always measure the quantity of urine passed in twenty-four hours. A patient may acquire uremia from kidney stasis due to ureteral distortion, constriction, or occlusion.

COURSE.

The course of a typical parametritis can be summed up in the following stages: 1. Infected area hard to map out, but tender and painful; 2, edematous, soft mass at edge of uterus in one of the various zones, presenting corresponding and marked symptoms as the edema increases; 3, exudate, increasing and spreading over toward the pelvis anteriorly, laterally, or posteriorly; 4, exudate filling pelvis in the zones of infection with accompanying abdominal tenderness and muscular rigidity, displacement of the uterus to opposite side of exudate, and beginning induration extending along lines of least resistance; 5, high temperature, pain, and tenderness increasing, with constitutional symptoms more pronounced, indicating abscess formation which usually happens on the eighth or tenth day. We make frequent blood counts; leucocytosis of 12,000 or over calls for surgical interference; we must not wait until resistance has been lowered; 6, cessation of pain, tenderness, and fever, and pulse recession indicate resolution.

The diagnosis is always digital and a metritis is

always present. The tubes and ovaries can be palpated only in the early stages. In the latter period they ride above the mass.

There is another form of parametrial infection. An uneventful puerperium may exist with the exception of slight discomfort and chilliness and a bare rise in temperature. It is wise to watch these cases carefully. Usually we are dealing with retained secundines, or the patient has received improper care. At any rate, she has an infection, and local resistance is retarding the typical signs of broad ligament disease.

In the meantime, however, slowly, insidiously, and definitely, a marked induration has formed in the broad ligament which at the end of three weeks can be felt encircling the uterine neck, toward the pelvic brim, and in the hollow of the sacrum. If a cervical laceration exists, it begins from the tear and extends to the side. The uterus may be displaced in any direction and the exudate may completely encircle the rectum, or be diffused to one side. The sacrouterine ligaments are thickened or shrunken and tense. The final manifestations may be psoas muscle adhesions, producing lower spinal deformity, painful walking, and marked neuralgias from involvement of the hypogastric and ganglion of Frankenhäuser in the form of severe psychiatric, crural, and pelvic distress. These patients present marked organic change in the form of chronic metritis, fibrosis, or atrophy and have frequent recurrence of spontaneous abortion or premature birth.

Next in frequency during pregnancy, abortion, or the puerperal state is pelvic peritonitis or perimetritis, brought about in the majority of instances from postpuerperal douches, washes, dirty instruments, or plastic operations. From a prognostic standpoint this is more serious because it may rapidly spread to general peritonitis. The condition arises from the tubes, the infection having reached them from the uterus. The resulting peritoneal extension is not controlled by the bacteria which have caused it, but by the amount of peritoneal response arising from virulence, resistance, and exudative propensity of its serous coat which controls the formation of the parametritic mass and adhesions. If the serous outpouring is so rapid that the adhesions cannot form because the lymph change does not take place, a rapidly filling cul-de-sac will soon present itself. On the other hand, if the abdominal opening of the tube closes up during the process of the reaction, the tube either ruptures, filling the cul-de-sac with pus, or it does not rupture, and following its normal direction outward, upward, backward, and downward, the tube falls behind the posterior peritoneal sheath, becoming adherent, the fimbria attaching themselves even down into and upon the floor of Douglas's pouch.

Perimetritis manifests itself either as a serous or a purulent cul-de-sac exudate, or an adherent annexal mass, adherent to all adjacent and surrounding tissues. Wherever the infected tissue comes in contact, serous and finally fibrinous adhesion takes place. The onset is stormy and the chill pronounced. The fever is continuous and high, and there is a corresponding pulse. Pain is not constant nor continuous, as in parametritis, and it is not localized to one side. Abdominal tenderness is more pronounced than vaginal. Meteorism and tympanitis usually occur, and nausea and vomiting are frequently present. Dry, heavily coated tongue and lips finish the picture of marked peritoneal irritation. Exudate formation varies, and involves only the cul-de-sac; it is never lateral, and is always behind the uterus, bulging into the posterior vaginal vault like a large egg. It increases downward, and the tubes and ovaries can always be palpated unless an extensive exudate is present. The uterus is pushed forward in anteflexion against the pubes, while in parametritis the displacement is forward and to the side. Parametritic exudate always begins at the lateral edge of the uterus and spreads over to the pelvic wall. Perimetritic exudate is always behind the uterus. The parametritic mass is fixed, while the cul-de-sac mass is movable. The former is hard and has an indurated feel, while the latter is soft and doughy. The posterior vaginal wall is thickened from cul-de-sac extension, and the exudate may burrow between the posterior vaginal and the anterior wall of the rectum; this will never happen in parametritis.

TREATMENT.

In the treatment of puerperal infection or septic abortion, the first point to consider is the presence of severe bleeding. It makes no difference whether fever is present or not; every case of severe bleeding calls for immediate and rapid interference. This is accomplished by careful digital curettage in the presence of fever, and combined digital and instrumental otherwise. The danger of hemorrhage overshadows that of infective extension.

It is always advisable to deal carefully with the curette. We never use a sharp curette—a dull, spoon shaped intrument is much better. The use of the curette in every pelvic infection is dangerous in inexperienced hands. Histories carefully tabulated show that a large percentage of severe septic explosions and a high mortality are directly traceable to its use in the early stages of these conditions.

It is poor surgery to enter the puerperal or aborted uterus, either digitally or with instruments, upon the mere suspicion of retained placenta and the presence of fever. I am strongly opposed to curetting the puerperal uterus unless the patient is bleeding or we are dealing with a sapremic condition and are positive that there is something in the uterus. First we try to establish these two points before interfering.

Sapremia always manifests itself with a marked odor, and placental tissue can always be felt upon exploration. When the temperature rises in these cases we are dealing with either septic endometritis, metritis, parametritis, or perimetritis. We must establish a definite diagnosis before doing anything radical, such as curettage. If the bacterial activity and extension are confined to the endometrium (which is rare), natural resistance has its hands full looking after the phagocytic and reactive formation. Is it fair to break down nature's work, open new areas of infection, destroy resisting ones, and stimulate septic absorption? The first principle in reactive inflammation is rest. Why should we disturb it with curette or digital destruction, thereby breaking up thrombophlebitic or lymphangiotic plugs for

further extension? On the other hand, is it not apparent that a curette will never reach the site of a metritis, parametritis, or perimetritis?

In every case of pelvic infection, it is not a question of retained placenta or secundines, but only and specifically a knowledge and consideration of the true variety and virulence of the bacteria causing the infection. To the general practitioner this is one of the most difficult problems. In hospital practice, better facilities are offered for frequent blood cultures, taking from twelve to twenty-four or forty-eight hours to develop. In the meantime, discouraging symptoms may compel interference.

Theoretical ideals classify interesting scientific principles, but they very often lead to unhappy results. The blood will give the resistance and antibody index, but will it always give the virulence of the aerobic leucocyte streptococcus we are dealing with? While we are waiting for the pathologist, the patient may die.

Winter, Walther, Voit, Shotmüller, and others have shown us that if bacilli coli communis or streptococcic bacteria are present it is safe to curette, but if the hemolytic streptococcus is present, we treat the cases expectantly, depending upon spontaneous placental expulsion, or later removal after bacterial virulence has abated.

I believe the matter is not a question of curettage as much as it is a question of drainage and, further, that the eye experienced in clinical signs tells more, and tells it more quickly than waiting for the microscope. The old theory that sapremia is always a local condition, while septicemia is a general one, has been exploded by Shotmüller, who has shown the streptococcus existing in each. Putrefactive and virulent hemolytic bacteria can exist together. If curettage brings the temperature down, virulent bacteria are absent and we are dealing with a toxemia; if it does not, they are present. Curettage, then, adds to their activity.

There are three cardinal points in treatment: 1, local; 2, drainage; and, 3, constitutional. It is better to utilize the three, and be on the safe side, than to adopt one and fail.

Infection in the pelvis is the same as infection in any other part of the body. An abscess may become circumscribed and walled off, throwing off its septic débris; or the virulent bacteria may overcome the wall of resistance, break through, and extend. The treatment in the former is locally operative by incision and drainage, but in the latter by further incisions and counterdrainage high above and along the site of original infection. In pelvic infection we have a local, adjacent, or general condition. If a foul smelling discharge is present we are dealing with saprophytic destruction, and the early indication for curettage exists. If, however, there is the slightest tenderness in the broad ligament, with or without an exudate, and the uterus is tender, we are dealing with a metritis or parametritis, and the treatment must go directly to and beyond the original site of infection.

The main exit of pelvic drainage is at the infundibulopelvic layer and base of the broad ligament; hence to these parts the treatment must be directed. We can accomplish this only by thorough and early pelvic drainage in the form of iodoform gauze strips placed fanlike through the cul-de-sac up to the infundibulopelvic and posterior layer of the broad ligament.

In the very early stages this is sufficient, but in the presence of an exudate, or abscess, we must also break into the broad ligament, and put into this space an extra iodoform gauze drain beside the others. We do not wait until an abscess forms, but drain as soon as the diagnosis is established.

We never curette a uterus unless we have a foul smelling discharge, and even then we supplement the treatment with pelvic drainage. What evidence have we that there are no virulent bacteria present? Pelvic drainage is the foresight of prevention, and is harmless in its application.

In perimetritis or cul-de-sac mass, drainage speaks explore the uterus with a uterine spoon scoop or our gloved finger, and if we find the uterus empty, we get out quickly. We depend entirely upon the pelvic drainage. We push streptococcic serum of the strongest polyvalent variety (twenty million), administered every three hours if necessary. We stimulate freely. High Fowler's position, Murphy drip, saline hypodermoclysis, active diuresis, catharsis, and diaphoresis help the patient more readily to eliminate and throw off septic material.

In perimetritis or cul-de-sac mass, drainage speaks for itself, and curettage is positively contraindicated until a later date.

In conclusion, I will say that a correct diagnosis of pelvic infection is the first essential. We do not treat the term as a disease but as a localized condition divided as to classification. In sapremia we curette and drain the pelvis; in septicemia or parametritis, we explore the uterus and drain the pelvis. We never curette when the broad ligament or annexa are involved.

In following these few simple rules as a principle, and making a careful, correct diagnosis, with timely and early treatment, we shall, in the majority of instances, bring about happy results and complete recovery in seemingly hopeless cases.

HEMIPLEGIA.*

Its Prophylaxis and Treatment.

By William Martin, M. D.,
Atlantic City, N. J.

The successful treatment of any condition means primarily the removal of the cause, but far better than cure is the prevention of disease. The present day prevalence of apoplexy, some cases quickly fatal, and others resulting in years of invalidism, makes this one of the real issues to be met by the medical profession. It is not only our duty to relieve the sufferings of those already afflicted, but we should do our best to point out means of prevention. When it is fully realized that many attacks can be prevented, there will be a better appreciation of the responsibilities that we should feel to be ours.

The purpose of this paper is to consider the sub-

*Read before the Burlington County, N. J., Medical Society, April 11, 1906.

ject of hemiplegia from the standpoint of prevention, as well as to take up the line of treatment of the secondary stage, or the so called chronic form. This is to be from the physiotherapeutic side, omitting drug therapy entirely, as drugs have been found inefficient in these cases.

The consideration of a subject of such vast importance will warrant a brief review of the etiology, symptomatology, and pathology of hemiplegia. No type of cases other than those of hemorrhage will be considered.

Hemiplegia is complete when the face, arm, and leg are all involved, and incomplete when only one or two parts are affected. The damage done by the hemorrhage depends upon the site of its occurrence. It may be in the motor cortex, it may affect the pyramidal fibres in the corona radiata and internal capsule, the cerebral peduncle, or the pons varolii. The facial effects are upon the same side as are those of the arm and leg, owing to the fact that the facial muscles stand in the same relation to the cortical centres, as do those of the arm and leg. This paralysis is partial, owing to an involvement of the lower portion of the nerve, but is usually well marked in character. It may involve the orbicularis oris in a slight way, and be perceptible only during emotion and excitement. When protruded, the tongue is deviated toward the affected side, which is due to the involvement of the hypoglossal nerve, and the lack of involvement and opposition of the geniohyoglossus of the sound side. With a right sided hemiplegia there may be aphasia, and when this is not present, there is usually a slowness and, at times, a difficulty of speech. As a rule the arm is most involved, but cases vary in this respect. The muscles of the thorax and abdomen always escape. This is explained by Broadbent by "supposing that as the spinal nuclei controlling these movements on both sides, constantly act together, they may, by means of their intimate connection, be stimulated by impulses coming from only one side of the brain." Sensory disturbances are variable. There may be hemianesthesia, but often there is only a numbness or slight impairment of sensation. When there is loss of sensation or sensory power, it is from a lesion in the retrolenticular portion of the posterior limb. Total anesthesia, according to Dana, is either functional or of subcortical origin, and is less common in hemorrhage than in softening.

Disturbances of the special senses are not constant, yet there are cases where there is some diminution of the sense of smell as well as of the taste and hearing. Gower thinks that homonymous hemianopsia of the halves of the visual field is of frequent occurrence, but often overlooked. In some cases under the writer's care there has been great impairment of vision, but it has not been definitely shown in each case to be the result of the hemiplegia.

In the second stage there is usually a return of the reflexes which were abolished during the active stage. The deep reflexes are increased, and there may be ankle clonus. The plantar and other superficial reflexes are usually lessened, and as a rule the sphincters are not involved. If, at the end of two or three months, there has been no gradual restoration of function, the paralyzed parts undergo certain changes. The leg may recover some power, but the foot drags. Secondary contractures or late rigidity appear, together with an exaggeration of the old symptoms, and these may be without further hemorrhage. The arm is usually more involved in these changes, and the rigidity may affect the elbow, wrist, and fingers, more than the shoulders. In some cases under the writer's care, the shoulder and fingers were most involved.

It has been stated that the leg contractures are not so painful as are those of the arm. In my experience the reverse has been true. Whether these patients have been suffering from contractures alone or with an associated neuritis, it has been hard to determine, particularly in cases where there has been no previous history of neuritis. In all there has been the usual favorable response to the treatment that would be applied to a neuritis.

The loss of power usually affects the muscles of the foot in a particular manner, and with the knee flexed in the effort to walk, there occurs the characteristic half circle swing of the foot. Late in the second stage, there may be some muscular atrophy, as well as other features that are not constant, such as tremor, athetosis, arthropathies of the affected side, and postparaplegic chorea (Osler).

Consideration of the etiology of cerebral hemorrhage brings us to the study of the conditions that apply to the cardiovascular system. As prophylactic measures suggest themselves by this study, they may as well be considered together.

The vessel changes that are the result of a persistent hypertension, frequently developing into arteriosclerosis, are potent etiological factors. As a primary cause of these changes we have various forms of poisons, intestinal toxemias from dietetic errors, and overeating, therefore care in eating as well as in diet itself, offers one measure toward prophylaxis. Meat proteins in excess appear at present to be held responsible largely for these toxemias, and with poor elimination, a growing hypertension becomes apparent, which if noticed early will be of little account, as it can be readily handled by ordinary measures. Exclusion of meats, using milk as a substitute, and allowing the vegetable proteins, together with other suitable food products, will do much to prevent an extension of the condition. As excessive eating is recognized as a factor, patients should be warned against it. These simple measures may prevent simple hypertension from progressing, but when not successful, more radical measures must be resorted to. Elimination must be kept free, and if constipation is pronounced, physical measures must be resorted to, as well as the use of mineral oil, agaragar, and occasional doses of castor oil. Colonic flushings may often be of benefit, preferably using the normal saline solution, and in quantity that will not overstretch and paralyze the bowel. Vibration over the course of the colon, and over the spinal centres that govern the abdominal organs, often acts efficiently. In addition, the sinusoidal current to these nerve centres is valuable, as by this method there is not only nerve stimulation, but increased peristalsis and secretions. Reducing the waste products by these

methods will counteract the morbid process which affects the depressor nerve, causing "constriction of the arterioles through which the anterior pituitary and the thyroid apparatus are supplied with blood," according to Sajous, who further states that "the supply of adrnoxidase (besides thyroidase) being diminished, the metabolic activity in the vascular walls is reduced, and the chief pathogenic process is thus controlled."

Massage may be used as an adjunct in suitable cases, bearing in mind that it acts in a manner similar to exercise, therefore in cases of high blood pressure it must be used with caution, if at all.

In all cases the frequent use of the sphygmomanometer is of great importance. Not only should the systolic pressure be taken, as is the rule, but the diastolic also, by which means that pulse pressure can be estimated. According to present day thought, the diastolic is the important one, if one only is to be considered, but in the writer's estimation it is best to take all, by which can be obtained the best information of the condition of the whole cardiovascular system. Leading the simple life, taking the proper amount of exercise and rest, all tend toward restoring cardiovascular tone. It is by such prophylactic measures that degenerative changes may be prevented. Here is where the family physician plays an important part, and if he meets the situation, he can be in position to save many a life.

So much for prophylaxis. In considering the treatment of hemiplegia from the purely physiotherapeutic standpoint, we must depart from the customary paths that have been well trodden for so many generations, and as this savors of the unorthodox, many may pass it by without investigation. As the measures that will be considered later have been well tested, they will be mentioned with the hope of their receiving favorable consideration.

In treating hemorrhagic hemiplegia we must bear in mind that the outcome depends largely upon the time that has elapsed since the onset, as well as the severity of the attack, and the personal idiosyncrasies of each case. Prognosis should always be guarded, as responses to treatment vary.

The first consideration is that of hypertension. Following the attack it is lessened, but when the patient applies for treatment in the secondary stage it has often risen to a dangerous point, and needs urgent attention to prevent recurrence. In some cases we find a condition of broken compensation, which means disaster.

To reduce the hypertension, we use the method of autocondensation. This is given from a high frequency apparatus that will deliver a d'Arsonval current. The couch upon which the patient lies has a cushion three inches thick made of floss or hair, under which is a metal plate of the same length and width, connected with one side of the apparatus. Reclining upon this couch, the patient grasps a metal handle which is connected with the other side of the apparatus, completing the circuit. The current is given in suitable amperage according to the needs of the case. It is rarely necessary to give over 650 m. a. of current, and often better results are obtained from a much smaller amperage, for instance, 350 m. a. The treatments last from twelve to fifteen minutes, and should be given daily, until the reduction reaches a point that is approximately the compensatory pressure. While it is impossible to determine this point definitely, it may be considered to have been reached when the circulation is at its best, and the patients feel best. This can be readily seen, as the mentality improves and various sensations disappear that have been disturbing to the patient, such as dyspnea, etc.

The effect of autocondensation is explained by de Kraft as follows: The warming effect of this current is different from that obtained by any other method. It occurs from within the body, not from without, and all of the cells participate. As a result of the heating of the blood and muscles, the entire heat regulating apparatus of the body is exercised, owing probably to direct stimulation of the sympathetic system. The blood is rushed to the surface, and the venous congestion is relieved. Splanchnic anemia ensues and visceral engorgements are relieved. The blood stream, returning to normal channels, carries a fresh supply of oxygenated blood to the various diseased parts, and as well all over the system. This equalizes the circulation and relieves the high pressure. The effect of this reduction of the cardiovascular load is at times wonderful, particularly upon the mental state of the patient. Cheerfulness and hopefulness replace dullness and melancholy, alone sufficient warrant for such treatment, contributing much toward a favorable outcome.

In addition to autocondensation we have mechanical vibration as a supplementary measure for reduction of the pressure. This is usually applied to the second and third dorsal interspaces for a period of five minutes at each treatment. This inhibits the functional activity of the vasomotor centre, permitting the bloodvessels to dilate. According to Foster, "blood pressure may be made to rise and fall by afferent impulses passing along nerves other than the depressor. The effect of the afferent nerve stimulation is similar to that caused by stimulation of the depressor."

If there is cardiac insufficiency, the vibration should be given also in the interspaces of the seventh cervical and first dorsal vertebræ. According to Dr. Arnold Snow, this probably acts through the pneumogastric nerve filaments of the rami communicantes which connect the sympathetic with the second and third dorsal nerves.

For restoration, as far as possible, of the muscle and nerve tone, we have the use of the slow surging sinusoidal and the interrupted constant currents. With these there are other modalities of value, but the two mentioned are perhaps the most used. The sinusoidal currents are of the smooth type, producing no painful responses, yet their action is most profound and energetic.

Its application is made by the use of well soaked pads of felt or cotton over metal, the larger or indifferent one being placed over the spine, the area chosen according to the part to be treated. If this is the arm, then the pad is applied to the lower cervical area, and if the leg, then to the dorsal portion. The smaller pad usually has a handle, and is applied in a labile manner to the motor points and muscles wherever needed. Treatments last about twenty minutes. For superficial effects the rapid sinusoidal

current is considered of value. Some forms of apparatus give a combination of the two currents, the rapid superimposed upon the slow, and this is said to have a decided effect upon restoration of the nerve cell tone.

If preferred, with the sinusoidal currents, there may be used alternatingly the interrupted galvanic. This latter has been for years the one preferred, but as it causes painful contractions, it is not so well borne by the patient, and this is soon made known to the operator.

For relief of spasmodic pains of the neuritic type so often seen late in the secondary stage, the static wave current offers the best means in a large percentage of cases. This is applied by means of a flexible metal plate about two and one half by six inches in size, wet, placed on the bare skin, attached to the positive side of the machine by a conducting cord or wire, with the negative side grounded. The amount is regulated by the separation of the discharging balls on the end of the sliding rods, the discharge of the current being interrupted at the rate of from 120 to 300 times a minute. Fifteen to twenty minutes is sufficiently long for each treatment, as it is not desirable to fatigue the patient.

This fatigue would be the result of too strong and too great an amount of muscular contraction, which acts in the same manner as so much exercise. The amount of pain caused by the treatment of the sore nerves will be another factor toward fatigue, therefore it is the better part of wisdom to proceed with caution as to the doses. The current is distinctly sedative in effect, it relaxes muscular spasm, and at the same time has a distinct metabolic action, by causing cell gymnastics. This is mainly local, but it also has some general effect, as the current is not confined to the area under the plate.

The matter of removal of the hemorrhagic clot has given the profession much thought. This is illustrated by the use of the iodides during the long past. Some have used cerebral galvanization with some degree of success, but the writer cannot speak from experience in this matter. It appears to be the logical method, granting that the current can be made to go directly through the skull and brain. This has been questioned by some, who state that the current follows the path of least resistance, which would be around the skull, thus not meeting the demands of the case. This questions remains to be solved.

By the outline given, it can be readily seen that the treatment of hemiplegia is largely symptomatic. The same holds true in drug therapy. Our present knowledge offers nothing better. After all, prophylaxis offers the best solution of the whole question, and it therefore behooves us all to be on the alert in the future, to teach our friends and patients the ways and means of guarding their lives so as to prevent this catastrophe.

Physiotherapy offers more than any other plan of treatment, when hemorrhage has actually occurred, if applied with common sense. It may fail signally, for after all, to use a modern phrase, "it is the man behind the gun" who counts more than any other factor.

Maryland and Pacific Avenues.

SECONDARY SYPHILITIC LESIONS OF THE TONGUE.*

By Constant Saison, M. D.,
Paris, France,
Ex-Intern, Paris Hospitals, Etc.

Secondary syphilitic manifestations on the tongue, although far less common here than on other mucous membranes, such as the lips, vulva, or anus, are not infrequently met. Those who have written on this subject are unanimous in this respect and in my own experience out of 617 patients with syphilis I found forty with lesions of the lingual mucosa. The mucous patch is unquestionably the most frequent, but, as I shall show, we may encounter the majority of the other elementary lesions which characterize the group of syphilides. Only, the seat of these lesions on an essentially motile organ, whose surface is unceasingly in contact with food, drink, and saliva, brings about differences in their external aspects which are often very great. In the study of these lesions the strictest account should be taken of the special structure of the lingual mucosa. This is not the place to describe the mucous membrane of the tongue; I shall simply recall the development of the papillary layer, the intimate adhesion of the mucous tissue with the underlying muscular layer, and lastly, the thickness of the epithelium, which is the seat of a continual and abundant desquamation.

All writers on syphilis have described lingual mucous patches, but usually, under this vague denomination they have included nearly all the lesions which may occur on the tongue during the secondary period. Certain other forms, generally of later manifestation, such as tubercular and ulcerative syphilides, have been confounded with the manifestations of the tertiary period, namely, the gumma. However, we must point out that this distinction has been made in recent years, particularly by Rollet, Gubler, Buzenet, and Julliard.

The erythematous syphilide, so frequent on other mucosa, particularly that of the isthmus of the throat, the first symptom of generalization of the infection in many cases, is at least rarely seen on the tongue, and the only reference to it that I have been able to find is by Rollet, who says: "Mucous patches on the tongue are sometimes composed of simple erythematous spots, smooth, surrounded by normal mucosa with its more or less projecting papillæ. This projection of the papillæ causes the erythematous plaque to appear depressed."

By what is expressed in this sentence it is seen that, in the mind of the author, this lesion enters into the group of mucous patches. Therefore, I shall not deal further with this syphilide, which I should not have mentioned, had it not been for the foregoing quotation, which drew my attention to the subject.

Of all the syphilides of the tongue, mucous patches are by far the most frequent, to such an extent, as I have already said, that some writers have comprised under this name all the secondary accidents. In my total of forty cases of lingual syphilis, thirty-five were mucous patches, eighteen being in males, fourteen in women, and one in a child with hereditary syphilis. Out of a total of

*Written expressly for the New York Medical Journal.

130 males presenting mucous patches, Basserlau found eighteen in whom the lesion was on the tongue, while Devasse and Deville noted six instances on the tongue out of a total of 186 females presenting this lesion.

It must not be inferred that this lesion is uncommon in children. The contrary is true, and the great frequency of mucous patches in the corners of the mouth, throat, and tongue in early life is known and explained as one of the ordinary ways of transmission of syphilis from nurse to infant, the breast being the seat of specific lesions.

The commonest site of lingual mucous patches is the dorsal aspect and borders of the tongue; they are often seated on the tip of the organ, less frequently on the inferior aspect. This difference in site also results in a difference in shape and aspect of the patches. Those seen most frequently have been described as opaline. On the top of the tongue it occurs as a slight elevation above a surrounding healthy mucosa, covered by a bluish white coating, almost transparent, in fact opaline, quite accurately likened to an area of mucosa to which nitrate of silver has been applied.

The shape of the patch is regularly rounded or oval, and with the magnifying glass, under the epithelial and fibrinous layers which form a kind of false membrane, we may see the papillæ projecting more than in the normal state, in themselves forming the relief of the mucous patch, which is simply an advanced degree of the preceding state. The patch may project much more markedly, forming true vegetating plaques; however, we never meet the large cauliflower patches on the tongue, such as are seen on the vulva and anal borders.

Often in these cases the grayish pseudomembranous aspect has disappeared and is seen only on the borders of the lesion. On the other hand, we sometimes observe ulcerations which connect this form with the ulcerating type. The forms that we have described differ greatly from the primitive type of mucous patch, for I have not spoken of the circumscribed raised edges nor of the central depression found on other mucosa, particularly on the lips and inside of the cheeks. This, I infer, is due to the essentially papillary texture of the tongue. As to a fetid secretion, the tongue, being continually moving and incessantly covered with saliva, drink, and food, does not present this to such a pronounced degree as other parts of the body. However, it must be said that where there are lingual mucous patches the breath is always disagreeable.

Beside the projecting patches, the top of the tongue is the seat of more or less deep fissures, with callous, white, punched out borders, with a fundus often difficult to see, unless the borders are separated by the fingers, and which is either ulcerated or healthy in appearance. Hot drinks and food are taken with difficulty by the patient.

The ulcerating form remains to be described and is found more frequently on the borders of the tongue, particularly where there is a point of irritation, such as a decayed tooth, at the two extremities of a space left by an extracted tooth, and in smokers who always place the pipe stem in the same place. Here we find large and deep ulcerations with indurated and projecting borders, covered by the characteristic whitish pellicle of a mucous patch and with a red bottom which bleeds easily. More often it is filled with a whitish detritus that is found in nearly all buccal ulcerations and makes the diagnosis difficult.

Sometimes the edges of the tongue present actual festoons of mucous patches, with ulceration, or at least deep impressions, opposite each tooth.

There is still one more characteristic which separates mucous patches on the tongue from those on other parts of the body, due to the manner of development and duration of the lesion. The mucous patch is one of the very early manifestations of the secondary period. Occurring after the roseola and general lymphatic involvement, it is contemporary with the papular syphilide to which it is related; its study is full of interest. Like the latter, the mucous patch appears in untreated cases at about the third month of the infection, usually disappearing much later than the papular syphilide and prone to recur. As to mucous patches on the tongue, although they may occur at an early date of the infection, at the same time as the roseola, for example, they may well appear at a much later date, from eighteen months to two years, for example. They are also much more stubborn to ordinary treatment, 606 being sometimes the only drug to have any influence on them.

As in other regions, lingual mucous patches may be transformed into vegetations, although this rarely happens. I will simply mention the pseudomembranous plaques described by Martin under the name of syphilitic diphtheria. They are as infrequent on the tongue as they are common on the lips and vulva. In the order of succession of syphilides, we meet only three forms which on the tongue represent the group of late syphilides, namely, the tubercular syphilide, ulcerating syphilide, and one other form that I have not found described in the textbooks and which I will, for the time being, call intermediary late lesion.

Secondary tubercles on the tongue are not a common lesion, but if we go carefully over the records of cases published under the head of lingual gummata, we shall come to the conclusion that not a few of these are, in reality, simply tubercles. For this reason I shall here record *in extenso* a case recently under my observation.

Case. E. Q., aged twenty-two years, entered hospital June 20th last. The patient had never been ill. Ten weeks earlier he had been treated at another hospital for a chancre, and while he was there a roseola appeared. He left hospital because he would not submit to treatment. Four or five weeks later, he noticed a generalized eruption of pimples, as he expressed it, and consulted a pharmacist who gave him some simple diaphoretic. The eruption continued to increase and he then consulted a homeopathic physician who treated him for a month without success. For the past six weeks there had been developing on the legs a number of scabs, as the patient describes them, under which considerable pus was found. Marked alopecia for the past month. No sore throat.

Status præsens. General debility with anemia. The entire body surface was covered with disseminated tubercles, varying in diameter from three mm. to one cm. Their surface was flat, slightly raised above the surrounding skin, and they presented the characteristic reddish brown color. On the back, the centre of the tubercles was slightly depressed and ulcerated, some being covered by a white, thin

exudate. On the arms we found, mixed with the lesions, a number of dark green crusts under which pus had accumulated. On the legs some of these crusts had disappeared leaving deep clean cut ulcers with a fungous base which bled readily.

At some spots on the back some of the tubercles were surrounded by groups of small papules which were beginning to be covered by a slight scab, and from their arrangement recalled the lesion which had been described as a stellate syphilide. At some spots the central tubercle had disappeared without ulceration, leaving behind a cicatricial depression surrounded by a broad, ham colored area presenting a few slight scales.

For six or seven weeks the patient had noticed that there was something on the tongue and lower lip. The lesion was indolent and he noticed it only because his tongue was very dry in the morning. On the dorsal aspect of the organ near the middle, five rounded ulcerations were seen, having a diameter of about 0.5 cm., isolated from each other, having a slightly indurated base, and limited by slightly raised edges. The lesions were of a darker red than the rest of the lingual surface. The bottom of the ulceration was a grayish yellow and partially filled with pultaceous matter of the same color. These lesions appeared to be similar to the ulcerated tubercles present on the cutaneous surface.

On the upper lip was a lesion which marked the transition of a cutaneous into a mucous tubercle. On the mucous portion was seen, as on the tongue, a grayish ulceration surrounded by an indurated raised edge, while that portion of the lesion situated on the skin presented an ulceration covered by a blackish scab.

The post cervical and inguinal lymph nodes were enlarged; those of the submaxillary region and floor of the mouth could not be palpated. Active specific and tonic treatment was instituted and the lesions soon began to improve.

I shall be brief in the description of lingual tubercle because it has an evolution quite the same as that occurring on other parts of the body. Beginning as a papule with a broad base, palpation shows that the induration exists in the entire thickness of the mucosa, but is quite independent of the underlying muscular structures. A certain number of lesions may be present, but they are always isolated from each other even when ulceration takes place. I have never seen them take on larger dimensions than one cm., and the ulcerations that I have observed have never taken on the serpiginous or phagedenic course sometimes met on the skin, particularly of the lower limbs.

The induration of the base sometimes extends a little in breadth, but never in depth. The edges are reddish brown, the fundus, more or less fungous and bleeding easily, is filled with a pultaceous detritus to which I referred when speaking of the mucous patch. The lesion which the lingual tubercle at this period most resembles is the primary chancre.

Whether the tubercle ulcerates or not, it always leaves a cicatrix which differentiates it from the mucous patch, but the cicatrix is not deep, is stellate in shape, nonretractile, and never involves the underlying structures, as is the case of gummata and various other lingual ulcerations.

Other forms of lingual ulceration are to be found in syphilitics which do not have the tubercle as a starting point. The recorded cases do not state the nature of the initial lesion giving rise to the ulcer, and in my own cases I have never been able to discover the nature of the original lesion; however, by analogy with what takes place in cutaneous ulcerating syphilides, it may be surmised that the starting point was a pustule. But since these lesions are indolent, the patients discover them only by chance or because there is a mechanical hindrance to mastication. Then the pustule, which is a very transitory element, has disappeared to give place to ulceration.

These ulcerations have a greater tendency to extend, to take on the serpiginous form, than those arising from tubercles. Like the latter, they do not react to any extent on the neighboring lymph nodes. They are indolent and often coincide with pustulocrustaceous or ulcerating syphilides on the skin, but they may occur without other specific lesion being present. It is in just such cases that the diagnosis is difficult and the real nature of the lesion is mistaken. But by taking a careful history of the case, and from careful consideration of the special characters presented by the ulceration, it is possible to make a correct diagnosis.

The cicatrix of an ulcerating syphilide of the tongue has much resemblance to that produced by a tubercular syphilide, and it only differs by the usually more considerable extent of its surface.

The limits of this paper prevent me from entering into a discussion of the late intermediary lesions to which I have referred; they coincide with other late secondary lesions, sometimes even with tertiary lesions. Suffice it to say that they are more indurated, with very irregular borders, and occur on the back and edges of the tongue. The fissures are deeper and their edges, which are indurated, are composed of hypertrophied papillæ. They never assume the opaline milky aspect of the mucous patch, even when they are of long standing. Usually they involve a considerable portion of the tongue, but do not give rise to an ulcerative process. I have not been able to convince myself that smoking has any influence in their production; certainly, giving up the use of tobacco does not cause them to disappear under treatment any more quickly, and I have seen them in patients who did not use the divine weed.

MEDICINE AND SURGERY IN MODERN WARFARE.*

By Benjamin Jablons, M. D.,
San Francisco,
Director of Laboratories, St. Francis Hospital; Formerly Pathologist, American Ambulance Hospital, Paris, France; and Bacteriologist, Morava Division, Serbian Army, War of Turkey and the Allies.

It is supposed to be a far cry from the day that Ambroise Paré operated on the field of battle, using heated irons to cauterize the bleeding stumps after amputations, while his patients lay in a dead faint from shock. Today—four centuries later—there are still places "somewhere in France" and "somewhere in Russia" where mediæval surgery holds sway and modern medicine and surgery is an almost unknown quantity. It seems as if cataclysmic upheavals of human passion and greed scatter to the four winds the knowledge that generations of physicians and surgeons have labored to amass.

It has been said by Weiting Pasha that the essential and proper conservation of the health and effectiveness of an army consists in the proper or-

*Read before the San Francisco County Medical Society, April, 1916.

ganization and administration of its sanitary service. It would be better to say that the effectiveness of an army is best maintained by the introduction of as much and if possible all of the modern methods that medical science has made available. The results obtained by those who most closely approximate the conditions that are present during peace, indicate most clearly their necessity even in times of war. It should not be considered impracticable when we realize that it has been possible for one nation to carry on an extensive warfare on four fighting fronts and be able to show at the end of almost two years of fighting a mortality of less than two per cent. The nation concerned does not owe this low mortality rate to any special knowledge on the part of its medical service. It is due to the fact that it has made it possible for modern scientific medicine and surgery to be utilized at the front. The higher mortality rate of the other combatants and their neglect of this measure are very apparent.

When war is declared, it becomes necessary for great bodies of men to be assembled at very short notice at places with which they are unfamiliar. This holds true for the members of the medical profession such as ours who are not required to familiarize themselves with military conditions. It is this unfamiliarity that leads to the belief that military medicine and surgery differ radically from the medicine and surgery of peace. This is not so, and most of the men who have had experience in military medical matters will bear this out. The conditions under which medicine and surgery must be practised are different, and it is these conditions that must be met and overcome before good results can be obtained. A knowledge of urgent surgery is essential on the part of those who are sent to the front as well as the ability to organize one's efforts so as to help the greatest possible number in the shortest possible time. This applies as well to the man in the dugout as to the man who is put in charge of a base hospital miles away from the front. It behooves both to realize that their help may be called upon suddenly for a tremendous number of the injured. Their service should be so organized that help can be readily and efficiently given. This does not apply only to surgical conditions, but as well to medical conditions. Epidemics are the greatest scourges of the war, infinitely more deadly than bullets. There are likewise certain conditions that arise during the war which necessitate special knowledge on the part of the physician. Where he himself cannot supply it, it is his duty to arrange to have access to this knowledge. In England, where compulsory military service was an unknown factor, prominent members of the medical profession have received military rank so that their services might be taken advantage of. Field consultants have been appointed, whose duty it is to go from hospital to hospital, control the work that is being done, and obviate mistakes that may occur. In France as well as in Germany medical congresses are held at the various posts so that men may be made familiar with the newest therapeutics and be taught to watch for unfamiliar conditions.

The organization of new or reserve hospitals is a contingency with which medical men should be familiar. When war is declared, it is invariably found that the number of existing hospitals is far insufficient to meet the demands. It becomes necessary to create new hospitals to take care of the increasing number of wounded and sick. The creation of these new hospitals necessitates likewise the creation of new executive positions. Physicians often entirely unfamiliar with hospital work find themselves confronted with the management and the administration of a large hospital. There is no opportunity even for investigation into a man's ability properly to conduct such a hospital. The hospital is created sometimes under the jurisdiction of the Government, sometimes under the jurisdiction of the Red Cross, most often by the generosity of an individual or group of individuals. Properly to equip such a hospital, realizing at the same time that it is a creation of a few months or of a few years only, is often a difficult problem. The easiest way out of the difficulty is to equip it completely with cheap, but durable apparatus, but it is essential, and this must always be borne in mind, that these hospitals be completely equipped in order that the results may be productive of good.

In Serbia, during the first and second Balkan wars, it was found necessary to convert armories, public schools, churches, and administrative buildings into hospitals. In those in which the equipment was fairly complete the results were good, although it was quite true that there was no reserve hospital in Serbia, let alone a military hospital, that did not suffer from want of equipment.

There are few countries today which are commonly classed as civilized that do not have modern equipment in their larger hospitals. What is more difficult is the creation of a modern hospital out of a preexisting building. In Serbia, at the time of the second Balkan war, some generously inclined individuals undertook to equip a vacant armory as a reserve hospital. After a few days of strenuous work they turned this hospital over to us with a tremendous feeling of pride. To our great astonishment their idea of completeness consisted in equipping the armory with about thirty beds, and 300 straw filled mattresses. The necessity of operating room equipment, of dressing room equipment, of a sterilizing outfit, of a portable dressing carriage within the wards of the hospital, such common things as bed pans and urinals, never seemed to occur to them. The installation of a bath tub for bathing the patients likewise did not seem necessary, although there are some people in Serbia who bathe regularly.

This is what will face many of us should a sudden emergency arise, and this is what the medical profession of America should be prepared for. The best example of what a reserve hospital should be, to my mind, is the American Ambulance Hospital of Paris. A consideration of the work accomplished, considering its inception and organization, demonstrates the necessity for thorough preparation. The ambulance now comprises fifty wards, with 575 beds, but with provision for 625 patients in case of emergency. Two general, one special, and two dental operating rooms have been equipped with the most modern appliances; two x ray plants have been

provided, and pathological, research, and dental laboratories have been installed. Sterilizing, disinfecting plants have been constructed, and ultraviolet ray apparatuses for sterilizing the water supply have been initiated on every floor. Six isolation wards have been prepared in a remote part of the building, and fifty rooms provide quarters and dormitories for the surgeons, graduate nurses, orderlies, and ambulance men. In the housekeeping department, the kitchen has been fitted with modern appliances, and has a capacity for supplying meals for more than 1,000 persons. Two mess halls have been arranged and furnished for the working staff. The offices of the various departments occupy fifteen rooms, and fifteen store rooms have been provided for food, and surgical and medical supplies. Workshops have been installed for carpenters, plumbers, electricians, painters, and locksmiths, as well as for cleaning and repairing the clothing of patients, and for repairing house and ambulance cars. The linen department has been provided with every facility for storing and handling clean and soiled linen, and arrangements with the American Hospital have placed its steam laundry at the disposal of the ambulance. A complete system of house telephones has been installed, and extensive work has been carried out in steam fitting, electric lighting, plumbing, gas fitting, installation of bath tubs, glazing, doorhanging, drainage, in fact everything required to transform a partially completed building into a modern surgical hospital. Finally, through the generosity of friends, and the collaboration of the municipal authorities of Paris, the unsightly grounds surrounding the hospital have been converted into lawns and flower beds and made available for convalescent patients and their friends.

The difference between a large, poorly ventilated, badly lighted, unhygienic, comparatively filthy armory, containing 600 beds, if a straw filled mattress can be considered a bed, and the foregoing is apparent, and may be said to mark the difference between medieval war medicine and surgery and modern medicine and surgery.

This brings us to the nursing during warfare. This is one of the most important matters that confront the military doctor in time of war. There are two classes of people that we draw on at such a time for nursing. There are the men assigned by the war office for nursing duty, who are as a rule untrained, not very strong, and not particularly efficient, and on the other hand, the horde of volunteers, made up very often of social butterflies, who are willing enough, but entirely unfamiliar with the drudgery and self sacrifice that nursing demands. The greatest number of the latter class lose interest very rapidly, and those that do not, find their lack of training a handicap that is not easily overcome. Their usefulness is limited very often by their awkwardness and lack of discipline.

In England, Kitchener in the early days of the war refused to permit any but properly trained nurses to be assigned to service at any one of the English hospitals in France. He, likewise, after consultation with the medical authorities, insisted that all volunteers undergo a course of training for at least six months in a base hospital in England before they were permitted to cross the channel. The soundness of this order is apparent today in the decreased mortality rate at the British hospitals on the continent, compared with that of other allies. This is a necessity in preparedness that must not be overlooked, and we sincerely hope that this precaution will be taken on the part of those to whose care the lives of our fellow countrymen are intrusted.

To whom shall this work be given? We are gradually outgrowing the idea that a medical degree is the only qualification necessary for a doctor in war time. We have realized that the soldier is as much entitled to special care, and the very best of care, when he risks his life for his country, as when he falls sick in the less trying times of peace. In fact, it may be said, he is entitled to better care, and that country that does not properly protect him in the event of sickness or injury is undeserving of his sacrifices. To get him off the field of battle quickly, to administer first aid immediately, to place him where the surroundings and care are such that his return to health is expedited, that is our duty.

The ambulance service is a very important item in France. The use of light automobile ambulances in conjunction with the sanitary trains, as well as the use of hospital ships, has greatly facilitated the transportation of the wounded. To go into detail in regard to the equipment of these ambulances would require more space than is possible in a short paper. It may be said in general that they should be equipped to render first aid, as well as to facilitate transportation of the wounded. At the base hospitals, this is comparatively easy of attainment, but at the very first dressing station, the application of modern medical and surgical principles is more difficult. The primitive life of the soldier in the trench as well as in the field, makes it impossible for the surgeon at the first field dressing station to administer anything more than elemental first aid. With a comprehensive arrangement it should be, and often is possible to remove the wounded or sick soldier in a few hours to a second dressing, or, as it is commonly called, casualty clearing station, where he can receive what may be properly termed up to date treatment.

In the English as well as the French army they have instituted mobile laboratories and automobile operating ambulances, making it possible to have as complete an equipment as is necessary for this kind of work. This does not obviously overcome the obstacles to quick removal of soldiers occasioned by continuous fighting. Tuffier has cited a case of a soldier who remained wounded in the woods of the Vosges mountains for eight days without help, and many of us have encountered similar cases.

What is to be done for the wounded is a subject that has agitated the minds of the leading medical men of the combatant nations. The lack of uniformity in treatment has in no small measure contributed to the mortality lists. Sir Almroth Wright and Sir Berkeley Moynihan have both insisted on the necessity of adopting a definite uniform procedure so that a patient may not be subjected to as many different kinds of treatment as the number of physicians he encounters. The following excerpt from the report of the American Am-

bulance Hospital in Paris indicates somewhat the nature of war surgery:

The cases treated may be divided into two general classes. First, gunshot injuries; a large majority of which have involved compound and multiple fractures, and, second, gunshot wounds of the face involving the maxillæ, and requiring the intervention of dental surgery. This latter class has greatly increased in number, owing to the unique facilities of the American ambulance for their treatment. The number of patients received during the year ending August 31st has been 2,622, of whom 1,968 have been discharged, cured or improved. One hundred and seventeen have died, and 537 remained under treatment. The death rate has been 4.46 per cent.

It would be erroneous to draw conclusions from the foregoing figures, but it may be stated that the chief factor of gravity for the patients has been the infection of their wounds, and that the intensity of infection has been almost absolutely proportioned to the interval of time between the injury and admission to the hospital. During the first half of September, 1914, patients were brought by our own ambulances directly from the battlefield to the hospital; almost all of these recovered with slight infection or no infection at all. The comparison with cases reaching us later on, six days or more after injury, is most eloquent in this respect. One infection in particular, gas gangrene, seems to be chiefly governed by this factor of delay.

In general, the patients received at the ambulance have received only first aid, or have undergone operations of an imperative nature before admission; at times, however, when it was necessary to evacuate hospitals nearer the front, patients have arrived who had been under treatment during extended periods. In jaw cases this delay has sometimes been so long as six months, resulting in most difficult conditions in the way of treatment.

There is another surgery that becomes necessary several months after the first casualties, and that is the surgery of repair, which includes the suturing of nerves, operations for late cerebral abscesses, plastic surgery of the face, eyes, and limbs. This is where the necessity for men trained in the specialties becomes very great. War medicine and surgery become then practically special medicine and surgery and the specialist is as much of a desideratum in war as he is during peace.

A Röntgen laboratory is absolutely necessary. It is to be wondered that efficient surgery could ever have been carried out in previous wars without this invaluable aid. Portable x ray laboratories are today a possibility, and no surgeon should attempt surgical relief of fractures or relief for any acute traumatic injury of warfare without having recourse to them. If a skilled röntgenologist is not available the surgeon should familiarize himself with the ordinary technic of screen examinations in order to aid in the localization of projectiles.

The removal of projectiles is still a subject of debate. Some insist that all projectiles should be removed, and base this on the assumption that most projectiles of modern warfare are infected the moment they enter the tissues. Some have even gone so far as to assert that the bullet, despite its rapid flight, does not sterilize everything it comes in contact with. I do not coincide with this view, and the recent researches on the presence of gas bacillus in wounds carried out by Rogers and Benet would seem to substantiate this. They found that shell fragments caused forty-two per cent. of all the wounds that they examined and were responsible for sixty-one per cent. of gas infections, while rifle bullets caused forty per cent. of the wounds and twenty-five per cent. of the infections. Tuffier insists that all projectiles should be removed and the pieces of clothing which invariably are carried in, be taken out. He has been instrumental in introducing the early disinfection of wounds. While this obviates in some measure the necessity for the removal of projectiles, the experience of those who have had occasion to see a great number of wounded soldiers leans toward the rapid and early removal of all projectiles when accessible.

With regard to the disinfection of wounds, the use of Dakin's solution, iodine, peroxide of hydrogen, and carbolic acid has been the subject of extended investigation, and still more extensive criticism. Pierre Delbet insists that the time honored antiseptics are just as capable of producing good results as the new fangled borated hypochlorite mixtures. Sir Almroth Wright would have it that wounds are best treated by the use of hypertonic citrated salt solution. There are others who maintain that the ideal method of treating wounds is to expose them to the air or to the concentrated light of several powerful electric lamps. The safest course to pursue is to use all of these methods. There are some cases that are best treated with strong antiseptics, there are others in which the more recently advocated methods are of great value.

The medical diseases most commonly seen are those produced by infectious agents. Typhus, cholera, relapsing fever, epidemic cerebrospinal meningitis, typhoid and paratyphoid infections, dysentery of the bacillary and amebic forms are most often met with. Weil's disease, now considered to be due to a spirochete, as well as relapsing fever, necessitate the use of the modern arsenical preparations, and the hospital that is not equipped to administer salvarsan or allied products intravenously cannot hope to obtain as good results as those that are equipped. The establishment of a convalescent home is likewise a factor deserving of consideration. Isolation hospitals for venereal diseases and for the highly contagious diseases of war help diminish the mortality rate.

We realize today that just as the aeroplane is a necessary factor in modern strategic warfare, so in the war that medical men carry on against the universal enemy, that medical aeroplane, the laboratory, becomes of prime importance. The Royal Army Medical Corps found it necessary to create mobile laboratories so that the diagnosis of infectious diseases in the trenches is possible at a time and place where its spread over a wide area may be prevented. Dysentery, typhoid fever, cholera, meningitis, all of these are diseases where early recognition is absolutely necessary for proper control. The physician or surgeon has not microscopic eyes. A soldier with colic or diarrhea does not necessarily have to be infected with the bacillus of dysentery, typhoid, or cholera. The unhygienic conditions under which he lives, the irregular ingestion of foods, the poor preparation of this food, all of these may produce an acute indigestion that indisposes only the soldier affected without in any way endangering his associates. Then again we have seen soldiers apparently well excepting for a slight diarrhea, who were responsible for a widespread epidemic costing thousands of lives. If it is impossible for a physician

or surgeon to carry out these measures, it is necessary that at least there be some one of easy access who can. The German army have appointed their most noted bacteriologists as consulting hygienists and their mortality rate is the best proof of the wisdom of this step.

In another country men who are very prominent in the field of bacteriology and medical research found themselves, three or four weeks after war was declared, applying bandages, stopping hemorrhages, and administering emetine tablets in the first *poste de secours,* work that any hospital steward or stretcher bearer could do with equal facility.

Several months after war had been declared some of the men who had not been captured and taken prisoners at Charleroi, were sent by a benevolent and all wise ministry of war to take charge of laboratories in which to combat the spread of infectious diseases. We cannot say what might have happened had these men been assigned at the very outset to work with which they were familiar, but the astonishingly good results of today, despite the extensive carnage, indicate that by the introduction of modern methods war has been robbed in a great measure of its horrors. To rob it of all its horror will evidently require much more than Hague conventions or Red Cross banners. We may hope that some day modern medicine and surgery will include war medicine and surgery, but until that time is ripe the only way to minimize the great loss of life and the suffering and unhappiness that war carries in its train is to make the military doctor a modern doctor.

Bush and Hyde Streets.

TREATMENT OF BLADDER AND URETHRAL PAPILLOMATA.

By Geza Greenberg, M. D.,
New York,
Chief of Clinic, Genitourinary Department, Northwestern Dispensary; Attending Urologist, German Hospital, O. P. D.

Within the last five years, rapid strides have been made in the treatment of papillomata of the bladder. Villous growths, which were formerly excised or cauterized either intravesically or suprapubically, and frequently recurred with great severity, are now treated with the most gratifying results by fulguration. Many pathologists look upon vesical papillomata as potentially malignant, and, while a large number of them finally prove to be so, this is not always the case. Some papillomata recur a number of times in the original form and do not metastatize, but produce local irritation with the various sequelæ of inflammation and infection. Death may follow the recurrent type of benign papillomata from hemorrhages consequent on severe ulcerations, or from renal infections when the neoplasms are near the ureters, causing first a hydronephrosis, and later pyonephrosis, renal calculi, uremia, etc. Others undergo malignant changes and metastasis.

Innocent looking villous growths may sometimes be malignant from the very outset, and if a section of such tumors is examined, the superficial layers may show nothing more than a benign papilloma while the deeper layers, which were not removed, may be distinctly carcinomatous. The question arises, therefore, How are such tumors to be dealt with?

Experience has taught us that such lesions recur repeatedly after operation, no matter how painstaking the technic, hence from a surgical viewpoint, all papillomata are potentially malignant, even though they do not metastatize nor cause a systemic intoxication. What should be the ideal way of dealing with such growths, in order to forestall possible recurrence without total extirpation of the bladder and transplantation of the ureters?

Since such radical surgical methods of treatment are not practicable, the safest and most expedient way is to destroy the tumor intravesically by either the Oudin or the d'Arsonval current. While growths were removed before use of the high frequency current by the galvanocautery, the results were not so good. The high frequency rays are extremely penetrating and destructive to the deepest layers of cells, and of the two currents, the d'Arsonval is the more penetrating, and the more lethal to cell life. From its action in the urethra, I have learned that it induces a mild or severe reactive inflammation according to the time of exposure and strength of current; the fibrin resulting from the action of the current on the exuded serum, probably stimulates the fibroblasts to activity, with the result of scar formation. It may perhaps act similarly in the bladder by cutting off its nutritive blood supply. The action of the high frequency current may continue for weeks after its application. I have seen growths disappear in weeks, and in one case, months after the application, which seemed ineffectual at first, had been discontinued. I observed also that it apparently induced a productive inflammation in a syphilitic urethra and stimulated the gummatous growths to greater activity; and the tissues were bathed in pus. In one case, it came from an infected and fistulous Cowper's gland, in another, from a prostatic abscess that discharged freely. It is possible that the persistence of the growths was due to the acrid discharges. The disposition of the tumor is not always the same, nor in all portions of the same growth, i. e., the villous processes dry up and drop off immediately, while the sessile portion shrivels up later.

I had occasion to fulgurate a large fibroid polyp, the size of a walnut, situated at the penoscrotal junction for a number of years. The whole tumor, except the base which was ulcerated and very painful, was fulgurated. Within four weeks, no trace was left. It did not drop off, but contracted to the level of the skin, and no mark was left on the former site. One exposure was sufficient.

Which current is best for the destruction of growths in the bladder? When the tumor is very large, for its greater penetrating action, the bipolar is to be preferred; while for smaller growths, the monopolar may suffice; care being taken not to injure the bladder wall. The action of the d'Arsonval current cannot be so well controlled as the Oudin. For all urethral polypi and papillomata, on the other hand, the Oudin is sufficient. To get the maximum amount of current, it is necessary to use

at least a quarter inch spark gap. Be sure that the Leyden jars are well supplied with salt water, and that the sound muffler and the sparking bar are freed from traces of nitric acid by washing them in water. The time of exposure varies with the patient, and the character and size of the growth. The tumor itself is insensitive to the current; the nearer the current to the bladder wall, the greater the pain. The treatment of tumors near the vesical sphincter is often painful, as is also the treatment of urethral growths. Usually, no local anesthetic is necessary for the average case of vesical tumor, unless it is situated near the sphincter. Under such conditions, it is best to anesthetize the whole urethra by injecting either one per cent. of novocaine into the urethra or cocaine 0.25, 0.2, or 0.5 per cent. Quinine urea hydrochloride, five per cent. freshly prepared, may also be used with good results, except that it is irritating at the beginning of injection.

The technic depends on whether the monopolar or bipolar current is applied. In either case, a catheterizing cystoscope is used. Through one of the catheter channels a No. 6 insulated copper wire is passed, the vesical end of which goes to the tumor to be sparked, while the proximal end is connected with the high frequency machine. The current is controlled by a foot switch. We turn on the current after the growth has been located, and apply it directly to every part of the surface until it is thoroughly blanched, when parts of the villi will be seen dropping off. The length of time of exposure will depend on the size and number of villi and the sensitiveness of the neoplasm. The treatment should be repeated once in ten days to two weeks. When the bipolar current is used, in addition to the wire in the cystoscope, a cord should be attached to the other pole of the machine, bearing a metal electrode which is applied to the body, either over the suprapubic region or to the buttocks of the patient. Instead of a body electrode, a rectal one may be used. This is more effectual than the former, particularly when the growth is near the sphincter. Special catheters are provided, with sufficient insulation, through which a wire is drawn and which terminate in a blunt point which does not injure the bladder wall. This, however, can be used only with the d'Arsonval current. When fulgurating, we always endeavor to get at the base of the tumor. In some of the large growths, this is impossible until we dispose of the superficial parts. The further the growths from the sphincter, the easier it is to destroy them. When situated at the sphincter, it may be impossible to reach them by the ordinary cystoscope, and under such circumstances, it is best to use a cystoscope with the fenestrum on the convex side of the beak, which may at times be utilized for the posterior urethra immediately in front of the sphincter. When a papilloma is so placed as to be absolutely inaccessible by ordinary cystoscopic methods, then it must be operated on by the open method, using the d'Arsonval current through the suprapubic opening.

It is still too early to state positively whether recurrences will be common after this treatment, and if they are, whether the malignant changes will be as apt to recur as after the old method of treatment. The reports of most of the urologists in this country are somewhat encouraging. Of six cases of vesical papillomata treated by me in the last four years, I have been able to follow up two.

Case I. Mr. L., forty-eight years old, came to me in March, 1912, with hematuria, pyuria, frequent urination, and dysuria. Cystoscopy showed a cauliflower excrescence near the left ureter, and a smaller one at the left upper quadrant of the sphincter vesicalis. The latter was richly supplied with distended loops of bloodvessels resembling an angioma. I first applied the Oudin current with no greatly encouraging results. Under the d'Arsonval current, the tumor disappeared completely after six applications. I then turned my attention to the other growth, which bled easily. Since the base of it was high up, behind and above the sphincter, not at all accessible, I advised operation. On opening the bladder, a small papilloma with a broad base was burned off with the cautery. On inspecting the bladder, no trace of the other tumor was seen. The patient made an uneventful recovery and was free from symptoms for three and one half years after the operation. At the end of this time, he returned with the following symptoms: Intermittent hematuria, difficulty of micturition, frequency of urination both diurnal and nocturnal. Cystoscopy now showed a large curtain overhanging and almost completely occluding the internal urethral orifice. It consisted of numerous villi. The base was at the left upper quadrant; the same site as the first one for which he was operated on, but the one which was fulgurated did not recur. Besides, there was a mild irritating cystitis due to incomplete emptying of the viscus. Under the d'Arsonval treatment, all the symptoms, together with the growth, disappeared.

Case II. H. B., of Summit, N. J., forty-seven years old, German, presented himself for pain in the left lower quadrant of the abdomen a little to the left of the hypogastrium; he also had pyuria. Cystoscopy showed a large, suspicious looking villous growth, with a very broad fleshy base, completely occluding the left ureter, so much so that the ureter could not be seen. The bladder itself was not infiltrated; the urine from the right kidney was perfectly clear and normal; the left could not be catheterized. The prostate was slightly enlarged, but not indurated. His left epididymis had been in a chronic state of inflammation for about six months. Wassermann negative. By eight treatments with the d'Arsonval current, the superficial villi down to the base disappeared. I then lost sight of the patient until a year later, when I could, for the first time, see the left ureter, which was large, patulous, and discharging pus. There was no trace of any tumor left. As a result of the long continued ureteral obstruction, he had, first, a hydroureteronephrosis, later a pyoureteronephrosis. I examined him again, about two and one half years after the fulguration treatment, and still found no signs of recurrence. At the beginning, he was rather discouraged with the slow progress of the treatment. He discontinued the treatment and still the retrogression of the growth continued until its complete disappearance.

When treating papillomata in the urethra, we must be extremely cautious with the strength of the current, on account of the great likelihood of stricture formation. We always use the Oudin for the urethra. I have seen a well defined stricture develop in the navicular fossa three weeks after fulguration.

From these and many other cases reported by others, we can deduce the advantages of this over the old methods of treatment. Some urologists even report the disappearance of papillary carcinoma of the bladder under its influence. I believe that in some cases of inoperable carcinoma, it should be used to check hemorrhage. Others again have reported its good effects in removing a median prostatic bar.

Whether or not it is more curative than the open operation, it has asserted its superiority over the old method, in that it is just as radical with more

conservatism, and the recurrences can be easily treated by the same process without seriously interfering with the patient's following the pursuits of his life. Some urologists in a few cases report hemorrhages to follow this mode of treatment. In my cases, I have not seen any alarming hemorrhages. I generally put patients to bed if there is bleeding, and in all cases as a routine, whether there is bleeding or not, I order cotarnine hydrochloride, three quarters grain, combined with fluid extract of ergot half to one dram, three or four times a day.

120 East Thirty-fourth Street.

AN INVARIABLE BLOOD STAIN.

Some Further Studies,

By B. G. R. Williams, M. D.,
Paris, Illinois.

So many good blood staining formulæ have been suggested to the profession that other methods seem to be uncalled for. However, about three years ago I (1) did propose one more stain and staining method, feeling justified for the following reasons:

1. The application of several dyes is a nuisance because of the necessary use of so many washing solutions, care in watching staining time, and the introduction of so many sources of error because of the complex technic.

2. The formulæ (Ehrlich's, Wright's, etc.) which fix and stain nuclei, cytoplasm, and granules, are easily applied, but do not give constant results. This criticism has been challenged, but I have witnessed poor stains where the worker was skilled and the solution properly made. It is a frequent observation that the more experienced the worker, the greater the number of failures. When the practical examination is approached, and especially if the number of blood spreads is limited, we need a method which is simple and yet invariable. We desire a technic and a solution which cannot fail, and which, regardless of the skill of the worker, will give usable results.

There are many hematoxylin and eosin combinations which are good, and this method is not stated by me to be original, except that after a study of eight years, I have finally hit upon a formula which seems to me to accomplish results which have never been realized before. The advantages over other methods are:

1. The technic is simple.

2. It is rapidly completed.

3. It gives results which are sufficient for diagnostic purposes.

4. It gives these results invariably.

5. It is practically impossible to overstain. No timing of the staining and washing is necessary. It is, in fact, a lazy man's method, but it is at the same time a busy man's method and no less valuable because of this fact.

PREPARATION OF THE INVARIABLE STAIN.

The hematoxylin used by me is the Ehrlich formula, which is made up as follows:

Mix:

Hematoxylin,	2
Acid, acetic, glacial,	10
Glycerin,	100
Alcohol, absolute,	100
Water, distilled,	100
Alum, potassium (an excess).	

Stop the container with a poorly fitting cork to permit some air to enter. Set aside for three to four months to let it ripen. Make certain that an excess of alum powder is present, and shake occasionally. Finally, filter the mixture.

The invariable stain is made up by adding to this filtrate, 0.1 gram of water soluble eosin. When this is dissolved, the mixture is ready for use.

FIXING THE SPREADS.

The invariable stain is not self fixing. Inasmuch as fixing provides perhaps the only source of error, I am inclined to place more emphasis upon the directions for fixing than upon the staining technic.

I use the alcohol-flash method of fixation, though it is possible that other good methods may answer.

First of all, light a burner, as this provides for prompt ignition of the alcohol. With a suitable forceps, seize the slide and hold with film face upward. Quickly cover the film with absolute alcohol and shake off excess by a quick movement. Immediately ignite the alcohol in the flame. Remove from the flame and move it from side to side through the air, in order to hasten the evaporation and the burning. The burning should not continue after about five seconds, but should practically flash. If the ignition is prompt and the alcohol absolute, no injury will be done to the film by either the heat or the alcohol. (If the spreading has not been properly carried out, but the films are too thick, they will soak up the alcohol and it will not flash.) When completed, the spread should be dry and perfectly fixed.

USE OF THE STAIN.

The directions are simple. After the slide cools, place it in a Coplin jar which has been filled with the invariable stain. After about fifteen minutes, the spread is stained, although better results are often obtained if it remains in longer; it will not be overstained by leaving in the mixture for several hours or days. Wash in water and dry by standard methods. The staining solution may be used indefinitely by adding to it from time to time, and keeping it covered to avoid evaporation.

RESULTS.

The picture is that given by any hematoxylin and eosin method. The nuclei are stained deep blue and the nuclear figures contrast nicely. The various granules take their respective tints. The results are satisfactory for all diagnostic purposes. I have not used the method for staining plasmodia. By the use of this stain, it is easy to diagnosticate the various anemias, leucemias, eosinophilias, and so on. Differential counting is much more satisfactory than with Wright's because of the excellent nuclear staining. The formula fills practically every qualification demanded of any blood stain.

It is not difficult to make up the staining solution, but when desired it may be secured ready for use from two large optical companies or from jobbers.

Contemporary Comment

The Increased Cost of Living.—It costs far more to practise medicine today than it did ten years ago. In the first place, the cost of living has doubled. Today the automobile is almost a necessity in general practice to give the quick service which the public demands. And to cap the climax comes the inflated cost of drugs—a serious consideration for the physician who dispenses.

Yet in many counties in this State, gloomily remarks the *Journal of the Medical Society of New Jersey* for September, 1916, medical practitioners are working for the same scale of fees their grandfathers worked under fifty years ago—when eggs were ten cents a dozen and garage charges were unknown.

Disease Dangers of War with Mexico.—The *Maryland Medical Journal* for September reprints from the *Journal A. M. A.* for June 24, 1916, the following comments: "Today these problems should be considered again. The State militia is mobilizing; large bodies of men are already being concentrated in camps, and soon, perhaps, some will be moving to the Mexican border, if not into Mexico. The guarding of the border is likely to be the duty which will fall particularly to the militia and less trained troops. Actual invasion, if it should come, will no doubt devolve on the regular army. Typhoid and smallpox vaccination have practically removed the menace to life from these diseases under military conditions. The militia, however, has not been immunized against typhoid even approximately to the extent that the regular army has been vaccinated. The danger from dysentery, which is still a menace to men in army camps, has been materially lessened through improvements in the preservation and protection of foodstuffs and through increased facilities for the transportation of supplies. Amebic dysentery may be prevented by strict supervision of water supply and filth disposal. The use of emetine in the treatment of this condition will aid in rapidly eradicating such cases as may occur. Malaria and yellow fever, conquered through eradication of the mosquito and prevention of mosquito bites, are no longer to be feared. Cholera, preventable by cleanliness, and typhus fever, the scourge of Mexico, also have been studied, and their prevention can be accomplished by the enforcement of adequate sanitary regulations.

The sanitation of camps has developed into a science. American investigators—many of them officers of the Medical Corps of the United States Army and of the Public Health Service—have led the way, and may be depended on to carry out these measures to the fullest extent. Typhus fever is particularly a Mexican problem. It has been a factor in the present European war, and the measures instituted abroad show how completely it may be controlled. Much has been said in connection with the European war of gas gangrene, tetanus, and secondary wound infection. The frequency of these infections has been attributed to the cultivation of the soil in the region in which the war is being conducted. If this is the cause, this condition is certainly not to be feared in Mexico. Much of the warfare in Europe has been trench warfare, and diseases peculiar to this method of warfare have frequently been discussed. The problem in Mexico would appear to be a different one. In any event, it hardly seems likely that the old saying that 'disease kills more men than bullets' will hold true.

We can be sure that American medical officers of every branch of the service will do all that is humanly possible to protect our soldiers in the field. As a result of their service, the American soldier will be safeguarded so that the maximum number of efficient fighting units will be continually available to those concerned with the action of troops at the front."

Is India's Caste System Doomed?—Maeterlinck, according to the *Lancet-Clinic* for September 9, 1916, termed his automobile "that dreadful hippogriff." The miraculous beast has shortened space and time, "the two great enemies of mankind." But this is as nothing compared to its effects on a system which has held one tenth of the human race in a grip of steel. Reference is made to India's caste system. According to latest advices from Calcutta, the automobile is making it practically impossible for people to flaunt their standing by elaborately decorated equipages, since motor cars look very much alike, regardless of ownership. Despite innumerable attacks on the long domination of the Brahmans, the ineradicable effect of the Sepoy mutiny on the inhabitants, the abolition of the suttee, the influence of British administration on the thought of India's millions, it was left to "that dreadful hippogriff" to accomplish what great world movements failed to do. No matter what destructive tendencies have been charged to the fabulous winged animal, its effect on the abolition of the caste system in India entitles it to the gratitude of mankind.

The Medical Knowledge of Cervantes.—In last week's issue, observes the *Boston Medical and Surgical Journal* for September 7, 1916, we commented editorially on certain medical aspects of Shakespeare's genius, and briefly reviewed some of the recent literature bearing upon this subject. It should not be forgotten that this year is the tercentenary of the death of Miguel de Cervantes Saavedra, to whose great power we owe, in Don Quixote, a character almost the equal of Falstaff, and whose interest in medicine is reflected in many passages of his great work. Doubtless in his case this interest was partly hereditary, for Rodrigo de Cervantes, his father, was a surgeon apothecary. Miguel himself, born in 1547, entered the Spanish navy, then the most powerful in the world and offering to young men an attractive career of adventure. It is narrated of him that at the battle of Lepanto he lay ill of a fever aboard his ship, the *Marquesa*, but insisted on going above to fight. He received two gunshot wounds in the chest, and a third which permanently disabled his right hand. Perhaps his personal surgical experience at this time, and later as a Moorish captive, further increased his knowledge of the medical profession, upon which many Spanish authors have written.

EPILEPSY AS A BAR TO MARRIAGE.

A case has recently been decided in the Supreme Court of Bronx County which is of particular interest to physicians. In this case, Elser *versus* Elser, the husband sued to annul the marriage upon the grounds that the defendant was physically incapable and that he was induced to enter into the marriage contract by her fraud in concealing from him that she was an epileptic. It was conceded that the defendant was at the time of the marriage and has since been afflicted with epilepsy. As to the first ground urged, it was shown that the exercise of the matrimonial function induced on the part of the wife paroxysms or convulsions symptomatic of the disease, and that this made copulation abhorrent to her and unsatisfactory to him, and thus lessened its frequency. In commenting on this particular phase of the case Mr. Justice Mullan said: "But as copulation was possible, no more need be said on that subject. As to the charge of fraud, I find there was none. I had a physician called to examine the wife, and he testified that statistics show that in about sixteen per cent. of epileptic cases covered by the records from which the statistics were compiled, the taint was inherited. The plaintiff's counsel urges that public policy requires an annulment decree in order to prevent the coming into the world of progeny tainted by an epileptic strain, but we have not as yet come to that refinement of civilization." The case was therefore dismissed without costs.

In the brief submitted by Charles S. Levy, counsel for the defendant, the decision in the cases of Gould *versus* Gould is cited (78 Conn. 242, page 266), in which the court says: "But no one has yet dreamed that the limits of this field of protective legislation can be extended beyond the citizens of today so as to embrace the citizens of all future generations." As the learned counsel remarks, "at present we have no remedial legislation in this State on the question of marriage which would raise the standard of children born in lawful wedlock. The question of eugenics is one for future legislators."

In the State of Connecticut it is illegal for epileptics either to cohabit or to marry, cohabitation without marriage rendering them liable to twenty years' imprisonment, while the marriage of epileptics, when the woman is under the age of forty-five years, renders the parties liable to imprisonment for not more than three years. We believe that Connecticut is the only State which takes cognizance of epilepsy in its relation to progeny. In New York State, as in other States, the concealment of communicable disease may under certain circumstances be considered ground for annulment of the marriage contract. In the communication which we publish on page 529 by Dr. Charles A. L. Reed, of Cincinnati, evidence is adduced that epilepsy is an infectious disease, though it has not hitherto been so classified. Should this contention of Doctor Reed be accepted it would have an important bearing upon any such case as that cited above. At present the courts are inclined to demand much stronger evidence to annul a marriage than is required to break ordinary forms of contract, and are averse to granting annulments for any cause except inability to perform the marriage functions. The comments in the case of Gould *versus* Gould, and the arguments submitted by the counsel in the foregoing case indicate a tendency toward recognizing eugenics as a factor in determining cases involving the domestic relations. As aptly said by Mr. Justice Mullan, "we have not as yet come to that refinement of civilization" which will justify the annulment of marriage because of the risk of producing unfit progeny, yet the trend of legislation is toward recognition of the welfare of the community as paramount to privileges and even rights of the individual.

THE SCHOOLROOM AND CONTAGION.

The schools open on September 25th; two million children in the State of New York are again to be confined within four walls. For five hours a day children in classes of thirty to sixty-five are to be brought in close contact and forced to endure rebreathed air. In most classrooms ventilation is poor; in some schoolhouses ventilating systems, theoretically good, have been installed, but through faulty planning or careless supervision the air is often vile. We recall that such was once the case even in an up to date normal school in Connecticut, where a $30,000 ventilating plant duly installed failed to function owing to the employment of an ignorant janitor's assistant.

Thus far bacteriologists and health officers have failed to convince the medical profession that anterior poliomyelitis is ordinarily spread by personal contact. Moreover, if there has been a true epidemic this summer, it is now at an end, and besides, children of the school age are in general immune to the disease. The real danger to children is from contagious diseases such as measles, scarlet fever, diphtheria, mumps, chicken pox, and especially the common cold. If school authorities take pains to see that teachers, superintendents, and head masters, the teaching force in general, and janitors of school buildings, are instructed in the necessity and method of providing effective circulation of clean air without causing drafts, not only will danger from contagion be minimized, but the working power of teachers and pupils will be greatly amplified. Probably one half the common nervous fatigue of teachers and most of the inattention and lack of interest of pupils is due to the stagnant, dusty, and too dry air of the schoolrooms. Whenever schoolrooms are badly ventilated and contagion results, in these days of enlightenment it is a question whether school boards may not be held, not only socially and morally at fault, but also legally and pecuniarily responsible for disease spread among children.

It has been clearly shown in many schoolrooms in the State of New York that an expensive system of ventilating is not necessary. A double layer of loose muslin cloth stretched over ordinary fly screens in the windows of the schoolroom is all that is needed to provide an ample supply of fresh air, without causing drafts. (See Dr. John B. Todd, Ventilation, this Journal for April 18, 1914, p. 785). This method of ventilation was adopted years ago most effectively in the Children's Hospital in Albany and elsewhere, and for a quarter of a century has been in use in many of the summer camps where contagious diseases are almost unheard of. Fine copper mesh screens in double layer are even more effective.

It has been conclusively proved in the French army that contagious diseases have decreased among armies in time of war to one third the number in time of peace. This is attributed to open air life and hyperoxygenation. In view of the justifiably critical attitude assumed by parents toward the negligence of school authorities and boards of health concerning ventilation, we look with interest to see what immediate action may be taken by the authorities to meet contagion in the schools.

REGULATION OF BODY TEMPERATURE.

Few problems in human physiology are of greater importance than that of the factors which combine to maintain body temperature at a nearly constant level irrespective of its surroundings. Few physiological problems, also, have proved more difficult of complete solution, and the sum of our accumulated knowledge leaves us incompletely satisfied. The study of thermal regulation in various classes of animals reveals all gradations, from the purely cold blooded, having a temperature essentially the same as that of their surroundings, through the hibernates to the nearly perfectly homothermal animals like man and the majority of mammals. The data derived from such studies afford interesting confirmatory evidence in support of the theory of evolution.

That there is no essential cellular difference between the several types of animals is shown by the fact that the individual cells of warm blooded animals respond to temperature changes in exactly the same way as do those of cold blood. It is, therefore, some difference in the organism as a whole which accounts for the homothermal character of the warm blooded animals. We have been able to discover the possible sources of the heat in these animals with relative ease and know them to be the combustion of nutrient materials during digestion and the functional activity of the several organs, chiefly the muscles. The loss of heat, we also know, is largely dependent upon the state of the peripheral capillaries and the activity of the sweat glands. The mechanism, however, by which these two prime factors—heat production and heat loss—are coordinated for the maintenance of a uniform body temperature remains somewhat obscure. M. S. Pembrey (*Lancet*, August 5, 1916) in discussing this subject points out that the homothermal animals cannot be distinguished from the cold blooded through the development of any special nervous structure for the regulation of temperature and says that we have no satisfactory evidence of the existence of special heat centres. He attributes the regulation of temperature to the nervous control over the muscles and glands and an increased sensitiveness to thermal change.

This view certainly offers a seemingly simple explanation of the problem and is supported by many clinical and experimental observations. Thus, muscular activity increases the temperature and the opposite condition lowers it. The effect of deep anesthesia is cited as supporting the view, but, as it reduces the animal to a state in which he responds to external temperature changes as does a cold blooded one, it seems necessary to demand some further explanation than the mere abolition or depression of glandular and muscular activity. The most logical explanation of this and other phenomena seems to be a depression of some central nervous mechanism which is normally sensitive to thermal changes or to their chemical results, and which acts as a coordinating and regulating centre presiding over the two opposed functions of heat production and heat loss. Such a view is strongly supported by the studies of Barbour and his associates (*Jour. Pharm. and Exp. Ther.*, v. 105, 1913, and vi. 1, 1914). This view, however, is not to be taken as necessarily implying the existence of any anatomically recognizable structure and, therefore, is not at all in conflict with the earlier statements we have cited.

VITAMINES AND BODY GROWTH.

The study of the vitamines is proceeding apace and our knowledge on the subject is forming into definite shape. According to Dr. Marvin D. Shie (*Medical Press and Circular*, August 23, 1916), who wrote concerning the effect of vitamines on body growth, the deficiency diseases, owing presumably to the absence or to the lack of vitamines in the diet, include osteomalacia, rickets, pellagra, beriberi, and scurvy. Probably many diseases will now be classed to a greater or less extent among the deficiency diseases. Shie points out, indeed, that recent researches have shown that scurvy is only one of a group of diseases which are induced by deficiency in the food of certain substances, minute in amount, but essential for proper nutrition. These substances are the vitamines. There are many articles of diet, such as potatoes, carrots, fresh vegetables, lime and other fruit juices, also certain animal foods, e. g., fresh milk, fresh meat, and yolk of egg, which are not only valuable for their nutritive constituents, but for their content of vitamines.

Dr. Carl Voegtlin is pursuing some valuable investigations along these lines into the causation of pellagra at Spartanburg, S. C. His researches and those of his coworkers have led to the belief that pellagra is due to a deficiency of vitamines. These investigations are still under way, however, but it may be anticipated that further work in this direction will result in considerably more light being thrown upon an extremely interesting subject and one of the greatest importance. Experiments by numerous workers in this field, and especially by Funk, have demonstrated beyond a peradventure that animals fed on certain diets, on foods deficient in vitamines, do not grow normally, but that when the vitamine element is introduced into the diet, growth becomes normal. Absence of fat in the diet causes suspension of growth in animals, but, as Shie points out, it is not the absence of fat *per se* that causes this suspension, but the absence of the vitamines in solution. Mendel and some others hold that there are several vitamines, one for the maintenance of health, one for growth, another for curative measures, and so on. Funk, however, denies this, and bases his opinions upon experimental investigations into birds. There is no more fascinating study and, at the same time, one of more practical value than that of the vitamines. By a thorough knowledge of them probably many diseases may be prevented and many others cured. It is becoming more and more evident every day that diet scientifically planned plays a great part in the attainment and preservation of health, and consequently in the prevention of disease.

A MEDICAL VIEW OF INSANITY BY A LAWYER.

We are frequently brought up abruptly against the radically different viewpoints of the physician and the lawyer in regard to mental disorder. Often, for instance, we are asked the question by one of the legal fraternity, "Is So-and-So insane?," an absolute positive or negative reply being expected, with no modification. Should the reply be in the affirmative, it is assumed that the subject must be immediately taken into custody, locked up, and henceforth have no rights or privileges which others are bound to respect. Such at least seems to be the theory under which most of the laws dealing with this subject are drafted.

It is refreshing in a recent article by a lawyer, Mr. F. A. Fenning (Protection of the Person and the Property of the Insane, *Case and Comment*, May, 1916), to find a distinctly different attitude toward the mentally ill. He speaks, for example, of the "hospital conception" of insanity, meaning that the insane person is first, last, and all the time a sick person who needs treatment. He speaks of the regulations in some jurisdictions which place the early handling of mental cases under the health authorities, in keeping with the theory that the insane person is sick, and not a criminal. This is also a recognition of

the fact that the first dealings with the disordered mind are of the most profound importance, and future ministrations are inestimably helped or hopelessly retarded by the nature of the attention given the patient in the early stages of his illness. It is a matter of common experience that the public court proceedings which feature nearly all commitments of mental cases, serve no real purpose, harass and humiliate the patient's relatives, and often have a pronounced ill effect on the patient himself.

The chief points made by Fenning are that the mentally ill person should be allowed to enter the hospital voluntarily on application, that he should be spared the humiliation of appearing in open court and being tried by twelve laymen, and that, after he has been entered in a hospital his estate should be administered in a manner harmonious with his best interests. Certainly from a medical point of view we can approve these contentions, and we hope that the future will see the medical and legal professions more and more in accord on this subject.

LONGEVITY AMONG OUR PRESIDENTS.

An anonymous letter to the *Lancet* for September 2, 1916, discussing longevity among great men, recalls that the longevity of the Presidents of the United States is remarkable. Their ages were as follows: 67, 90, 83, 85, 73, 80, 78, 79, 68, 71, 53, 65, 74, 64, 77, 56, 66, 63, 70, 49, 56, 71, 67, 58 years. Those at fifty-six, forty-nine, and fifty-eight were respectively, Lincoln, Garfield, and McKinley, who were assassinated. The ages of these twenty-four men totalize 1,663 years, or an average of sixty-nine years each, showing, as is believed, that the stress and responsibility of leadership seem to have no effect on longevity. The following causes of death are those popularly accepted: Washington, pneumonia (more correct accounts state edematous affection of the windpipe or membranous croup); J. Adams, debility; Jefferson, chronic diarrhea; Madison, debility; Monroe, debility; J. Q. Adams, paralysis; Jackson, consumption and dropsy; Van Buren, asthmatic catarrh; Harrison, bilious pleurisy; Tyler, bilious attack (with bronchitis); Polk, chronic diarrhea; Taylor, cholera morbus and typhoid fever; Fillmore, debility; Pierce, dropsy and inflammation of stomach; Buchanan, rheumatic gout; Lincoln, assassination; Johnson, paralysis; Grant, cancer of the tongue and throat; Hayes, paralysis of the heart; Garfield, assassination; Arthur, Bright's disease, paralysis, and apoplexy; Cleveland, debility; B. Harrison, pneumonia; McKinley, assassination.

Medical Education of Women in Scotland.—Miss S. E. S. Mair and Mrs. A. M. Chalmers Watson, on behalf of women medical graduates, students, and their friends, have offered to pay to the Edinburgh University $20,000 for the medical education of women.

Prevalence of Poliomyelitis in the United States.—Reports received by the United States Public Health Service, in Washington, D. C., show that the undue prevalence of infantile paralysis is limited for the most part to New York city and communities in the vicinity. The disease has not spread to any great extent in epidemic form, many States even reporting fewer cases this year than during the corresponding period in 1915.

The New United States Pharmacopœia.—Although unbound copies of the ninth revision of the *United States Pharmacopœia* were sent out to the press in July, bound copies were not delivered until about September 14th. The publishers, P. Blakiston's Sons & Company, of Philadelphia, have promised early delivery on all orders which have been placed with them. Notwithstanding the fact that copies were not obtainable, the work became the legal standard on September 1st.

The National Formulary.—A new edition of the *National Formulary*, the fourth, has just been issued by the American Pharmaceutical Association and under the National Food and Drug Act has become the legal standard for the articles and drugs named in it. The propaganda committee of the New York State Pharmaceutical Association has issued a select list of abstracts from the new pharmacopœia and the new formulary which are being distributed to physicians through the members of that association.

The Fourth District Branch of the New York State Medical Society held its tenth annual meeting in Plattsburg on August 24th, under the presidency of Dr. J. B. Ransom, of Dannemora. Over seventy-five members attended and the meeting was of unusual interest. The following officers were elected: Dr. Leo H. Finch, of Amsterdam, president; Dr. T. A. Rogers, of Plattsburg, first vice-president; Dr. R. A. Hutchins, of Ogdensburg, second vice-president; Dr. F. J. Ressenguie, of Saratoga, secretary; Dr. G. H. Oliver, of Malone, treasurer.

The American Pharmaceutical Association held its sixty-fourth annual meeting at Atlantic City, N. J., September 5th to 9th. Dr. Solomon Solis Cohen, of Philadelphia, a member of the committee of revision of the United States Pharmacopœia, delivered an address on The Physician and the Pharmacopœia. The session was presided over by Dr. W. C. Alpers, of Cleveland, president, who created a sensation by criticizing severely the financial management of the association. Doctor Alpers will be succeeded by Dean Wulling, of the school of pharmacy of the University of Minneapolis. The association will meet next at Indianapolis at a time to be selected.

Personal.—Dr. Hermann M. Biggs, State Commissioner of Health of New York, is in Rochester, Minn., where it is reported that he will undergo an operation for some abdominal lesion at the Mayo Clinic.

Dr. Albert A. W. Ghoreyeb, teaching fellow in pathology, Harvard Medical School, will deliver a course of fifteen lectures on first aid before the Women's Educational and Industrial Union of Boston. The first ten lectures will cover the subjects outlined by the first aid department of the American Red Cross.

Dr. Herbert R. Brown, assistant director of the Massachusetts State Department of Health, has accepted the position of pathologist to the Rochester Homeopathic Hospital, Rochester, N. Y.

Dr. William G. MacCallum, professor of pathology at Columbia University, who has been traveling since February, will return to New York this month. During his trip he visited, among other places, Honolulu, Fiji, New Zealand, Java, Borneo, and Sumatra, devoting some time to a study of the diseases prevailing in those countries.

Dr. A. D. Bush, of the department of biology of Olivet College, Olivet, Mich., and author of a valuable series of articles on modern treatment now appearing in the New York Medical Journal, has been appointed head of the department of pharmacology and therapeutics of the University of Southern California.

Dr. Charles W. Pilgrim, superintendent of the Hudson River State Hospital, has been appointed president of the New York State Commission in Lunacy.

University of Pennsylvania Hospital to Receive the Jeannes Fund.—Dr. Winford H. Smith, superintendent of the Johns Hopkins Hospital, Baltimore, who was selected by the trustees of the Jeannes Fund to go to Philadelphia, make a survey of its hospitals and medical work, and give them his opinion as to where the money would be of the greatest benefit, has recommended that it be given to the University of Pennsylvania Hospital. The fund, which amounts to more than $3,000,000, is the estate and its increment of Anna J. Jeannes, a noted Friend philanthropist, who died in 1908. According to the terms of her will the money is to be used for the treatment of cancer, nervous diseases, and disabling disorders.

United States Public Health Service.—Congress has recently made an appropriation for thirty-three additional assistant surgeons in the United States Public Health Service. These officers are commissioned by the President and confirmed by the Senate; the tenure of office is permanent, and successful candidates will immediately receive their commissions. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon; passed assistant surgeons, after twelve years' service, are entitled to examination for promotion to the grade of surgeon. Assistant surgeons receive $2,000, passed assistant surgeons $2,400, surgeons $3,000, senior surgeons $3,500, and assistant surgeons general $4,000 a year.

Cases of Poliomyelitis According to Age Groups.—Statisticians of the Department of Health of the City of New York have completed a survey of the cases of poliomyelitis by age groups, which have been reported since the outbreak of the epidemic. Of the 7,496 cases under consideration, 751, or 10 per cent., were found among children under one year of age; 5,662, or 75.5 per cent., among children between one and 5 years; 812, or 10.8 per cent., among children from 6 to 10 years; 142, or 1.9 per cent., among children between 11 and 15 years, while 129, or 1.7 per cent., among persons of more than 16 years of age. Children between 2 and 3 were most often the victims. There were 1,714 of these. Of children from one to 2 years old, 1,541 were victims, while those from 3 to 4 years numbered 1,278. Children from 4 to 5 years of age numbered only 618.

New Tuberculosis Directory.—Announcement is made that a revised edition of the Tuberculosis Directory compiled by the National Association for the Study and Prevention of Tuberculosis is ready for distribution. The present book of 421 pages records more than twice the number of activities included in the previous volume. The 1911 edition listed 1,500 agencies, while the present edition contains record of more than 3,100 different organizations and institutions engaged to a greater or less extent in antituberculosis work.

The following table, which is included in the introduction to the directory, gives a brief summary of the present status of the campaign in the United States:

Sanatoriums, hospitals, and day camps for the treatment of tuberculosis	557
Boarding houses for consumptives in health resorts	158
Hospitals for the insane making special provisions for their tuberculous patients	90
Penal institutions making special provision for their tuberculous inmates	35
Dispensaries, clinics, and classes for the special treatment of tuberculosis	455
Open air schools and classes for children	310
Associations and committees for the study and prevention of tuberculosis	1,324
	2,929

In addition the directory lists the following number of Canadian institutions and associations: Sanatoriums, hospitals, etc., 35; dispensaries, 14; associations, 109; total, 158.

A copy of the directory will be sent post paid on receipt of the price, 60 cents. Address request to the National Association for the Study and Prevention of Tuberculosis, 105 East Twenty-second Street.

Ohio Valley Medical Association.—Plans are being made for the annual meeting of this association, which will be held in Evansville, Ind., on November 15th and 16th. Among the speakers will be Dr. J. H. Kellogg, of Battle Creek, Mich., Dr. Curran Pope, of Louisville, Dr. Martin Fischer, of Cincinnati, Dr. William Schimer, of Indianapolis, Dr. J. Rawson Pennington, of Chicago, and Dr. W. F. Bogges, of Louisville. Dr. G. M. Young, of Evansville, is president of the organization, Dr. B. L. W. Field is secretary, and Dr. J. C. McClurkin is chairman of the committee of arrangements.

Changes in the Medical Faculty of Boston University.—The following changes in the faculty of the school of medicine of Boston University have been announced: Dr. Samuel A. Clement, instructor in contagious diseases; Dr. Alberta S. Guibord, instructor in psychoanalysis and psychotherapy; Dr. Francis H. MacCarthy, clinical instructor in diseases of children; Dr. Howard Moore, lecturer in orthopedics; Dr. Elizabeth Ross, lecturer in bacteriology; Dr. Helmuth Ulrich, lecturer in hematology; Dr. Frank C. Richardson's title on the faculty has been changed from professor of neurology and electrotherapeutics to professor of nervous diseases; and Dr. Alonzo G. Howard has been made full professor and the head of the new department of orthopedic surgery, with Dr. Howard Moore as lecturer.

Medical Society of the Missouri Valley.—The twenty-ninth annual meeting of this society will be held in Omaha, under the presidency of Dr. John P. Lord, Thursday and Friday, September 21st and 22d. An interesting program, both scientific and social, has been arranged. Among the guests are Dr. Jabez N. Jackson, of Kansas City, who will deliver the address in surgery; Dr. Walter N. Bierring, of Des Moines, who will give the address in medicine; Dr. Robert H. Babcock, of Chicago, who will read a paper on Bronchial Asthma; Dr. C. W. Hopkins, chief surgeon of the C. & N. R. R., who will read a paper on First Aid to the Injured; Dr. Fred Moore, medical superintendent of public schools in Des Moines, who will read a paper on Acidosis in Children, and Dr. R. T. Vaughan, of Chicago, who will give an illustrated lecture on Cartilaginous Exostoses. The complete program contains twenty-three papers to be read and discussed. Dr. Charles Wood Fassett, of St. Joseph, is secretary of the society.

Vital Statistics for the Month of July.—Despite the epidemic of infantile paralysis, the death rate in Manhattan and the Bronx was lower during July this year than during July last year. In the other boroughs the deaths from poliomyelitis were so numerous that they not only offset the reduction in the mortality of the other diseases, but raised the death rate above that of last July. The mortality of the following diseases was lower during that month than during July, 1915: Typhoid fever, measles, scarlet fever, diphtheria, other epidemic diseases, all forms of tuberculosis, cancer, heart disease, and diarrheal diseases. Particularly noteworthy was the reduction in the mortality of the diarrheal diseases, and since the greatest reduction in the mortality of these diseases has been in the age group under one year, it cannot be fairly stated that this reduction has been caused by a transfer of diagnosis to poliomyelitis, because the deaths from the latter disease have been most numerous between one and five years of age.

Considered from the viewpoint of age grouping, there were fewer deaths in the age group under one year of age and in all the age groups over fifteen. Between the first and the fifteenth year the mortality was much heavier during the past month than during the corresponding month of last year. Altogether there were 6,209 deaths reported during the month in the greater city. Of these 2,696 occurred in Manhattan, 561 in the Bronx, 2,997 in Brooklyn, 771 in Queens, and 184 in Richmond. The rate for the city was 13.04, as compared with 12.53 for the corresponding month last year. During the month 4,244 marriages were reported, equivalent to a rate of 8.91. This was a slight increase over the number reported during July, 1915, when 4,023 were reported, equivalent to a rate of 8.67. Births to total of 11,145 were reported during the month, compared with 11,466 for the corresponding month of last year, the respective rates being 23.42 and 24.71.

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
University of Southern California.

Thirty-sixth Communication.

TUBERCULOSIS.

Certain essentials are demanded by the body for its constructive work. The first of these is a supply of the food principles of such proportion and content as may be necessary to maintain adequate reparative processes and to keep the energy requirements of the body above normal kinetic demands. A second essential is such a supply of atmospheric oxygen as will be sufficient for all combustion requirements. A third essential is free clearance for all worn-out, unutilized, and waste products, whether exogenous or endogenous. There being no drug of demonstrated utility in the treatment of tuberculosis, and the serum treatment not yet having passed beyond the unsatisfactory experimental stage, the chief line of attack against the great white plague is to place the natural defenses of the body in the most advantageous condition possible. Therefore there should be continuous life in the open air in an environment of as little atmospheric contamination as the resources of the patient will permit. For anabolic ends the nutrition supply of easily digested food is pushed to the gastronomic limit, the object here being so to saturate the tissues with available energy as to make possible a supranormal elevation of cellular resistance; when this object is attained the reparative and curative processes are definitely established, resulting in a permanent cure after a considerable time.

Care must be constantly exercised that purin metabolism does not result in undue retention of anabolic products. The nitrogen balance may be readily studied through frequent examinations of the urine, and any adverse showings can be promptly corrected by suitable adjustments of the diet.

Exercise is usually strictly limited at first, so that the major portion of the available energy may be utilized for defensive purposes. As evidences of the curative processes develop, graduated exercises prove beneficial in promoting the capacity of the body for metabolic interchange, and to this end may well be judiciously encouraged.

In attacks of tuberculosis the infective organism slowly progresses on its insidious way until the defenses of the host are inadequate for resistance. This is possible simply because the patient's powers of resistance have been lowered by other deteriorating influences, or because the reaction-sensitiveness is relatively dull to this particular germ process. In either case the great necessity is to adjust the metabolic processes of the patient so as to permit the highest possible development of the somatic forces normal to the maintenance of robust health. In other words, the bodily conditions, both intrinsic and environmental, must be so developed that anabolism exceeds catabolism, with a wide margin of safety; over and above the normal metabolic equivalences, there must be developed a fighting reserve wherewith the body may successfully overcome the invading bacilli and neutralize the debilitating toxemia. Then, too, the environment must be such as to admit of the least possible impingement of adverse influences.

Any agent that serves to combat disease has a pharmacological significance; therefore, in a series of papers like the present, we are justified in discussing matters of hygiene whenever the application of these hygienic principles involves therapeutic ends. At this point it is safe to reiterate that the sole purpose of administering a therapeutic agent is to render more or less timely assistance to harassed nature. Nature in any event effects whatever cure may be attained; the drug or measure used simply serves to render more efficient nature's offensive and defensive operations.

(*To be continued.*)

Post Mortem Cæsarean Section.—J. A. Harrar (*American Journal of Obstetrics*, June, 1916) discusses the management of pregnant women suddenly dying undelivered. Many infant lives have been sacrificed through the confusion attending the catastrophe or the embarrassment or inability of the attendant or his inability to obtain consent for operative maneuvres upon the dead mother. Yet the legality of post mortem Cæsarean section even without the husband's consent has been demonstrated, and where such consent is not obtainable, while the fetal heart is still beating, it is not only permissible but imperative that the physician should immediately do everything in his power to save the child. Attempts at extraction made by version or forceps generally fail, unless death happens to take place during the second stage of labor. Among fifty women dying undelivered in the New York Lying In Hospital, post mortem delivery was undertaken in nineteen instances. Version was done seven times, but uniformly resulted in stillbirth. Two children whose mothers were already in the final phase of labor were extracted living through the normal passages. On the remaining ten women Cæsarean section was performed; only three of these were in labor at the time of death. Four died of heart failure, two of eclampsia, and one each of cerebral hemorrhage, tuberculous meningitis, ruptured uterus, and hemorrhage of placenta prævia. Of the babies, three were stillborn and had probably died before their mothers. Four were born with hearts feebly beating, but could not be resuscitated. Two were resuscitated, but died later. Finally, two were discharged living and well—one having been extracted by Cæsarean section immediately after death in the apoplectic case, and the other seven minutes after death from broken compensation in mitral

stenosis, the woman having been in labor nine hours. Obviously the success of the operation depends much upon the promptness with which it is done. That the operation should not be performed if the fetal heart sounds are inaudible is a wrong conclusion, as not infrequently babies are born normally whose heart it has been impossible to auscultate. Several valuable minutes may be lost in attempting to detect the heart sounds. Thus Cæsarean section should follow maternal death immediately, unless one already has positive proof that the baby is dead. Asepsis may be ignored, the abdomen and uterus being simply incised quickly and freely and the child extracted. Stress is laid on persistence in efforts at artificial respiration as long as any intermittent contraction of the infant's heart can be felt by pressing the fingers up under the left costal margin.

Clinical Comparison of Wound Dressings.—Dermer, at a meeting of the Société de chirurgie (*Presse médicale*, July 20, 1916), reported comparative studies of the effects of various antiseptics in 943 wounds of industrial—not military—origin; 101 injuries were treated with hydrogen dioxide, 175 with potassium permanganate, seventy-five with ether, 135 with Dakin's solution, and 457 with magnesium chloride solution. The preliminary treatment was the same in all cases. All the antiseptics, except Dakin's solution, were used as washes and wet dressings, while Dakin's solution, as in the Carrel method, was applied by continuous, drop by drop irrigation. Two facts were clearly shown: First, that Dakin's solution, in general, gives better results than the other antiseptics, and second, that the length of stay in the hosptial in cases treated with magnesium chloride was only about one half that in cases treated with Dakin's solution. Evidently magnesium chloride, used in fresh wounds as an accelerator of phagocytosis, is capable of yielding notably good results.

Definite Treatment of Pneumonia.—Solomon Solis Cohen (*Canadian Medical Association Journal*. August) divides treatment into general and special. Under the former he includes: An abundant supply of fresh air, preferably in the open, with due care to preserve the warmth of the body by adequate covering, and if necessary, external heat. 2. All the essentials of good nursing, including rest, proper diet, and the free use of water internally and externally. Copious diuresis is sought. 3. Keeping the thorax warm by poultices during the day and a lamb's wool jacket at night. This may be preceded in early cases by a mild mustard and flour poultice. 4. A due supply of chlorides either by saline infusion, alkaline-saline beverage, or by administration in capsules followed by copious drafts of water. 5. Such additional measures of elimination and alkalinization as may be necessary. 6. Cleansing and relative disinfection of the upper air passages by local applications to the throat and nose of phenoliodineglycerin, or silver preparations, or by continuous inhalation of volatile antiseptics, such as ethyl iodide, creosote, chloroform, or terebinthinates. This general treatment represents a groundwork upon which the definite medication is superimposed. Under special treatment comes first an antitoxic agent. Quinine is given promptly in massive and repeated doses with progressive lessening of the quantity and increase of the interval according to effect; the drug being intermitted when the mouth temperature tends to remain below 102.5° F., and resumed when it tends to rise above 103°. This medication may be kept up for one, two, or three days. There may be only one dose, or as many as fifteen. The rule is effect, not quantity—enough and no more. Quinine and urea hydrochloride, twenty-five to fifty per cent. solution by intramuscular injection through the iodized skin, is on the whole the most effective preparation and method. but other quinine salts are used. Next are pressor agents. Cocaine hydrochloride, caffeine sodiosalicylate, adrenaline, and posterior pituitary principle, are used singly or in alternation or rotation when necessary to maintain the line of systolic blood pressure at or above the level of pulse frequency. The pituitary principle has the additional advantage of tending to prevent tympanites and dilatation of the stomach. Usually a precautionary injection of cocaine, or of posterior pituitary solution, is made with the first injection of quinine, since the latter tends to lower blood pressure slightly. It is repeated every third hour, or as needed. In some cases as many as sixty doses have been given, in others from three to ten, in some none at all. Next come the cardiants, camphor or digitalis in full doses, to regulate the diastolic blood pressure and respiration. Sometimes both of these agents are employed, but in the majority of cases neither is needed. Digitalis effects can be obtained more readily when the patient is under the influence of quinine than in other cases. Care must be taken with both pressor agents and cardiants not to exhaust by overstimulation. One must be neither too bold nor too timid. Oxygen sometimes is helpful. Auxiliary and symptomatic measures include wet cupping, dry cupping, venesection, and the continuous or occasional use of oxygen, alcohol, strychnine, atropine, opium, musk, creosotal (ammonium carbonate), and other drugs reserved for special indications which may or may not be present in any given case. Cases calling for early bleeding are not often seen, but late bloodletting to relieve the right heart is called for occasionally, and may prevent death from pulmonary edema if done in time. Tincture of ferric chloride is given when the quinine is withdrawn, and is continued during convalescence. In prolonged cases with extensive lesions, in certain cases of tardy defervescence, and in all cases of delayed resolution after defervescence, an autogenous vaccine is used in progressively increased amounts at appropriate intervals under the guidance of temperature and leucocyte reactions. The early employment of bacterins does not seem to be advisable or beneficial. In all features of the treatment there must be a careful adjustment of means and measures to the special needs of the particular patient at the moment. We must not only know when and how to use medicines, we must also know when to withhold them. All of the measures are not to be used in every case, in most but one or two will be needed, but in some several will be indicated. Routine is inferior to discretion. Too much is worse than too little, but too little is not good, the aim being to be just right.

Tuberculous Laryngitis.—J. William Wright (*Indianapolis Medical Journal,* August) recommends that, aside from the general treatment of the pulmonary tuberculosis, every patient at intervals not greater than one month should have a careful examination of the larynx, and at the first sign of a laryngitis should receive the proper treatment. Fewer laryngeal complications would ensue if this were done. All nasal deformities should be corrected. Overuse of the voice, faulty phonation, and needless hacking and scraping of the throat invite the inflammation. He has found that a solution of five per cent. menthol and five per cent. guaiacol in olive oil injected endolaryngeally will alleviate the desire to clear the throat and will give a rest to these parts. If there is much thickening between the arytenoids, he touches the tissue with crystals of trichloracetic acid, and after the slough has come away the voice usually is much improved.

Tuberculosis of the Tongue.—James R. Scott (*American Journal of the Medical Sciences,* September) states that tuberculosis of the tongue is of more common occurrence than is supposed; it occurs more frequently in males than in females; it is met during all age periods of life, but is most common between the fortieth and the fiftieth years; and it occurs in two forms, primary and secondary. The greater number of cases are secondary in character. Clinically it may assume different types, such as the ulcerated, fissured, granulomatous, and papillomatous. The differential diagnosis involves consideration of simple ulcers, the local manifestations of syphilis, carcinoma, and epithelioma. The treatment may be either medical or surgical. Medical treatment offers little hope of ultimate cure, and should be used only in advanced cases, or when the lingual process is accompanied by a generalized tuberculosis. The rational treatment is surgical in nature, complete excision of the involved tissues and the surrounding healthy tissue for some distance.

X Ray Treatment of Uterine Hemorrhage.—Robert T. Frank (*Surgery, Gynecology, and Obstetrics,* September, 1916) sums up as follows: 1. The Röntgen ray produces amenorrhea by destroying the ovarian follicular apparatus, or oligorrhea, by partial destruction of follicles. The resulting menopause symptoms correspond in character and degree to those of the postoperative menopause. 2. The choice lies between two methods of application; a, the fractional-weak, requiring prolonged use, but readily controllable; b, the intensive-massive, more readily producing amenorrhea. 3. Obstinate cases of hemorrhage in adolescents can be cured. Only cases such as have resisted all other forms of therapy should be selected. 4. Functional hemorrhages during sexual maturity, if conditions are unmistakable, and curettage shows absence of carcinoma, may be relieved by producing oligorrhea (with the possibility of subsequent pregnancy) or be definitely cured by inducing the artificial menopause. 5. Preclimacteric functional hemorrhages are readily cured by the production of the menopause. At this age, malignancy must be even more carefully guarded against. 6. Uterine fibroids may be slowly reduced by x ray treatment. All complicated cases should be excluded, as otherwise serious or fatal mistakes may occur. In properly selected cases (five to ten per cent.) the choice between operation and Röntgen therapy may be left to the patient. In patients with serious heart lesions, nephritis, or pulmonary trouble, or in the hyperneurotic, preference should be given to the x rays.

Autoserotherapy in Gonococcal Orchitis.—Wagon (*Bulletin de l'Académie de médecine,* July 25, 1916) reports four cases of gonococcal orchitis with serous effusion in the tunica vaginalis in which reinjections of this fluid yielded gratifying results. The fluid was obtained by stretching the skin over the tunica vaginalis, puncturing it with a sterile hypodermic needle—avoiding veins—and allowing the fluid to run out through it into a sterile syringe. After the tunica vaginalis had been evacuated, the needle was withdrawn and one c. c. of the fluid injected under the skin of the thigh, with usual aseptic precautions. These injections proved painless and were not followed by any reaction. In each case immediate benefit was noted, the pain being relieved and motion of the parts rendered less uncomfortable. In two instances fluid failed to reappear in the tunica vaginalis. A cure uniformly followed the treatment in six to eight days, the patients being then able to resume their occupations without any precaution other than wearing a suspensory bandage. On the whole, the procedure seemed to constitute an ideal specific treatment for gonococcal orchitis, safe as well as simple, and available under all circumstances.

Treatment of Infected Wounds.—Rutherford Morison (*Lancet,* August 12, 1916) states that as the outcome of experience with infected, suppurating war wounds, the following simple plan of treatment has been developed. With the patient under an anesthetic the wound is covered with gauze soaked with one in twenty phenol and wrung out. The skin about it is then cleansed with the same solution and the wound opened freely, care being taken to avoid damaging the larger vessels and the muscular branches of nerves. The cavity is then cleansed with a Volkmann spoon and dry, sterile gauze. Next the wound cavity and surrounding skin is mopped with alcohol and the whole wound is filled with a paste of the following composition:

℞ Bismuthi subnitratis, ...30.0;
Iodoformi, ...60.0;
Petrolati liquidi, ...q. s.
M. et fiat pasta.

When completely filled with the paste, the wound is covered with a dry, sterile gauze dressing and an absorbent pad. Usually the dressing can be left unchanged for days or weeks, unless there is pain or constitutional disturbance. If a discharge comes through the dressing the spot must be soaked with alcohol and a gauze dressing, wrung out of alcohol, applied over it. The treatment avoids frequent change of dressings, and has given entirely satisfactory results, even in severe compound fractures in which it seems to stimulate osteogenesis. No iodoform poisoning has resulted from the use of the paste in large quantities.

Pharmacology of Emetine.—Emil J. Pellini and George B. Wallace (*American Journal of the Medical Sciences*, September, 1916) present the findings of a series of experiments from which they conclude that emetine depresses and may eventually paralyze the heart; that it is a powerful gastrointestinal irritant, whether given by mouth or by subcutaneous injection; that it causes a definite derangement of metabolism characterized by an increase in nitrogen loss and an acidosis; and that, while in normal persons who receive moderate doses these effects may not be of importance, in pathological states of the circulation, intestinal tract, or metabolism, they may be a definite source of danger.

Radical Treatment of Duodenal and Gastric Ulcer.—John B. Deaver (*Annals of Surgery*, September, 1916) concludes that all ulcers of the duodenum or stomach are best treated by excision. In the presence of a strong clinical probability of gastric ulcer supported by positive x ray evidence or by doubtful findings under palpation and inspection, he does not hesitate to perform gastrotomy in order to settle the matter by inspection of the mucosa. In the individual case, the advisability of excision depends upon the local condition. No ulcer should be excised when subsequent closure and anastomosis present too great operative hazards. It is in such cases that operations which depend upon drainage and alteration of gastric chemistry have their field.

Treatment of Chancroid.—Goubeau (*Presse médicale*, July 24, 1916) at a meeting of the medical staff of one of the French army corps recommended the following treatment: The surface of each chancroid is first carefully freed from pus with pledgets of cotton dipped in ether. It is then painted, either by means of a camel's hair brush or a small rod around which a little cotton has been tightly wrapped, with the following preparation:

℞ Sodii arsenatis, ...1 gram;
Alcoholis, ...50 grams.
Misce.

The arsenate being relatively insoluble, the preparation is a suspension rather than a solution. The next step consists in causing the alcohol to evaporate rapidly by blowing air over it with a cautery bulb, bellows, or through a piece of straw. A thin film of sodium arsenate becomes deposited and penetrates into the recesses of the chancroid. Immediately after, the suspension is painted on again and again evaporated. Finally, a dressing of sterile gauze is applied. The treatment is repeated daily. Repetition for more than three or four days is rarely required. At the end of this time the chancroid is transformed into a healthy red wound which tends rapidly to heal. On each subsequent day the lesions are washed with ether and covered with powdered iodoform. This treatment yields more rapid results than any other, a cure generally resulting in eight or ten days. Where bubo occurs as a complication, Goubeau obtains quick results by injecting directly into it, one c. c. of a one per cent. aqueous solution of sodium arsenate. This is repeated, if required, on alternate days. Where an abscess has formed, it is evacuated by puncture with a small trocar and the arsenate injected immediately after.

Radium Treatment of Uterine Cancer.—Joseph Rausohoff and J. Louis Rausohoff (*Annals of Surgery*, September, 1916) summarize this form of treatment as follows: 1. Radium is the method of choice in the treatment of inoperable and borderline uterine cancer. 2. In three operable cases treated with radium a clinical cure has been effected in all. 3. Cases clinically curable by radium should not be subjected to hysterectomy, as the operation is difficult and dangerous.

Exophthalmic Goitre.—W. B. H. Aikins (*Canadian Prac. and Review*, August, 1916) states that proper medical care will give as large a proportion of good results as will surgical, and is preferable by far in most cases. All the symptoms seldom disappear, no matter what treatment is employed. The first essential in medical treatment is the enforcement of prolonged, absolute physical and mental rest, preferably in the country. With this there should be a course of full feeding, excluding from the dietary all foods which are rich in extractives. Of the many drugs recommended, few are of value, but among these the most serviceable seems to be quinine hydrobromide. This may be combined advantageously in the following prescription:

℞ Quininæ hydrobromidi, ...0.3;
Ergotini, ...0.06.
M. et fac tales cachetas vel capsulas. S. One three times daily.

Organotherapy, including the use of rodagen, thyroidectin, and antithyroidin gives favorable results only in a small proportion of cases. The use of x rays applied over the thyroid has proved decidedly beneficial, but better results are secured by the local application of radium. The latter is preferable to x rays on account of the possibility of greater accuracy in regulating the dose.

Goitre.—J. J. Link (*Medical Standard*, August, 1916) recommends, in addition to the constant ingestion of thyroid gland preparations, rest, avoidance of all excitement, good hygienic and pleasant surroundings, change of mind from all former worry and anxiety, for it has been shown plainly that anxiety, worry, anger, and fear have increased hyperthyroidism. For the tremor and mental excitement, phytolacca, strontium bromide, and the tincture of salix nigra have given the author satisfaction. These drugs often suffice to control the tachycardia, but sparteine and strophanthus are sometimes indicated. Serums obtained from the glands of thyroidectomized animals have been given with somewhat varied results by hypodermic injection, as well as by the mouth, but when good results were obtained they lasted only so long as the serum was employed. Pulverized milk of thyroidectomized animals has been employed. In some cases the results from cytotoxic serum have been gratifying, but the serum is not uniformly successful. Iodine injected into the thyroid gland has had some effect, but not a lasting one, and any permament effect that may have been produced is due to its cauterizing or shrinking effect upon the gland, thereby reducing its hypersecretion, but not altering or counteracting the fluid. He states that the surgical treatment for Graves's disease undoubtedly gives the most satisfactory results under proper presurgical care with skillful operators.

Treatment of Pellagra.—E. M. Perdue (*Texas Medical Journal,* August, 1916) states that pellagra can be prevented by the drinking of water containing a sufficient quantity of the bicarbonates of calcium and magnesium. It is cured by the simple means of administering a simple and suitable alkaline carbonate or an organic alkali convertible into a carbonate.

Treatment of Herpes zoster.—Lewis H. Adler, Jr. (*Pennsylvania Medical Journal,* August, 1916) gives liquor potassii arsenitis, six minims, four times, daily. Locally the parts are cleaned with a two per cent. creolin solution and freely dusted with borated talcum powder. Over this a wad of absorbent cotton is applied and kept in place by a suitable bandage.

Digitalis in Aortic Incompetence.—Seymour Taylor (*Lancet,* July 15, 1916) believes that digitalis is contraindicated in aortic insufficiency when uncomplicated by other valvular lesion. Not only is it of little or no benefit to the patient, but it seems to increase materially the tendency to sudden death typical of this disease. There is one condition only in which digitalis is helpful and not dangerous—namely, when the aortic incompetency is complicated with mitral incompetency.

Wound Treatment.—C. W. Duggan (*Brit. Med. Jour.,* July 15, 1916) has found that the use of eusol or other forms of wet dressings in the treatment of open wounds will produce a clean healthy granulating surface, but the further healing of the wound does not progress well. Much better results can be secured by the substitution of ichthyol or glycerin, which may be used from the outset if desired. Under these agents the wound will be made clean and granulation is stimulated so that healing is rapid.

Intestinal Catarrh, Typhoid, Dysentery, and Mixed Infections.—Arneth (*Berlin. klin. Woch.,* February 28, 1916) discusses his wide experience of these analogous conditions as seen among the troops and gives the following as his treatment in cases of intestinal catarrh. An initial dose of castor oil is followed by 200 grams of bolus alba mixed with sufficient boiled water. The diet should be restricted to weak tea and thick gruels, and water should be forbidden. After the first day red wine is given and two doses daily of a half gram each of tannalbin. Benefit is also derived from the application of an abdominal binder for warmth. In cases without fever three doses of one mil each of tincture of opium should be given daily with the treatment just outlined. In typhoid and dysentery, the initial dose of castor oil should be omitted, but the rest of the treatment is the same. In bacillary dysentery small doses of a mixed Flexner and Shiga antiserum should be given as early as possible. Tannigen is twice as strong as tannalbin, and is decidedly preferable to the latter in dysentery, and either is to be preferred to bolus alba for controlling the movements. Additions to the diet should be made slowly in cases of dysentery, for rapid increase is often followed by relapses. No addition should be made to the diet until the stools become more or less formed. When using the antiserum an initial dose of twenty mils is given, and this, or even double the quantity, is repeated every day or two.

Lumbar Puncture for Eclamptic Convulsions.—W. T. Wilson (*Jour. A. M. A.,* Sept. 2, 1916) reports two cases of persistent, oft repeated convulsions occurring in eclamptic women, to show the striking, immediate, and permanent control of the convulsions which were brought about by a single lumbar puncture in each. Not only were the convulsions checked, but other symptoms, such as coma and suppression of the urine were relieved. The spinal fluid seemed to be under pressure in both cases.

Treatment of Miliaria.—P. G. Unna (*Berlin. klin. Woch.,* February 21, 1916) remarks that this condition is similar to miliaria tropica and cheiropompholyx, and is characterized by small vesicles filled with serous fluid having an alkaline reaction and containing leucocytes and mast cells. Its chief symptom is itching, though where the skin is moist it may be complicated with eczema. It is apparently of infectious origin. Its treatment is simple and satisfactory, consisting in the application of a drying, antiparasitic powder such as is provided by either of the two following prescriptions:

℞ Sulphuris, ...
Zinci oxidi, ... } .....āā 2.5;
Magnesii carbonatis,
Talci, ... } .....āā, ad. 50.0.
M. et S. Apply freely.

℞ Pulveris ichthargani,
Magnesii carbonatis, } .....āā 25.0.
M. et S. Apply freely.

Treatment of Local Tuberculous Processes.—Defontaine, at a meeting of the Société de chirurgie (*Presse médicale,* July 20, 1916), reported excellent results in the treatment of tuberculous abscesses and tuberculous involvements of the joints, lymph nodes, and skin by means of injections of a solution of guaiacol and iodine in ether:

℞ Guaiacolis, ...gtt. v;
Tincturæ iodi (Codex), ...gtt. xij;
Ætheris, ...10 c. c.
Fiat solutio.

The solution is prepared immediately before use. A quantity of it, varying from a few drops to one half c. c., is injected daily or on alternate days at one or two points of the tuberculous lesion under treatment. While a large injection may cause considerable though evanescent pain, injections of small amounts cause little or no pain, and may be repeated frequently. Any notable local reaction indicates that smaller amounts should be used. The needle to be inserted into the disease focus should be as fine as possible; ordinary hypodermic needles suffice, but must be available in different lengths, in order that the deeper foci may be reached. Large calibre needles predispose to sinus formation. By this form of treatment Defontaine succeeded in arresting and curing previously active white swellings of the shoulder, knee, and wrist which would otherwise have required resection. Many glandular swellings commonly opened by the bistoury, were likewise caused to retrogress. In tuberculosis of the skin the procedure gave results rivalling those afforded by x rays, and presented, furthermore, the advantage of being available to all practitioners.

Miscellany from Home and Foreign Journals

The Intravenous Administration of Iodides.—D. K. Averbuch (*Roussky Vratch*, May 14, 1916) reports in a preliminary contribution his results in obtaining a combination of iodine which could be introduced into the circulation in large doses. He found the combination of benzol, amines and iodine—dioxybenzolaminoiodide—to be perfectly safe when administered intravenously. The preparation is an amorphous, brownish yellow powder, with a faint odor of iodine and iodoform, slightly alkaline reaction, freely soluble in water. When administered intravenously to dogs and rabbits, no reaction follows unless the preparation is not pure. The preparation was administered to fifteen persons, in doses containing 1.5 gram of pure iodine, without any untoward results. Further investigations are promised.

Gastrointestinal Findings in Acne vulgaris.—Lloyd W. Ketron and John H. King (*Jour. A. M. A.*, August 26, 1916) state that the acne bacillus is generally recognized as the direct cause of acne vulgaris, but a number of associated conditions probably act as predisposing factors, among which gastrointestinal abnormalities seem of special importance. Clinical observations recorded in the literature point to the frequency of such disturbances in acne subjects, but no scientific studies have been made. The authors investigated the problem by x ray examination and gastric analyses in a series of patients with acne vulgaris, and found gastrointestinal abnormalities present in every case. In sixty per cent. of the cases these were of sufficient severity to have caused gastric and intestinal stasis and toxic absorption. Ninety-three per cent. showed gastric abnormalities, seventy per cent., intestinal. The commonest conditions found were hypacidity, atony, gastric retention, and ptosis. In the intestine the commonest were cecal stasis, colonic ptosis, and adhesions in the ileocecal region.

Medical Diathermy.—E. P.-Cumberbatch (*Archives of Radiology and Electrotherapy*, August, 1916) states that metal electrodes can be made of sheet lead and should be of a thickness of one mm. Useful stock sizes are: Circular 4, 6, and 9 cm.; rectangular 4 by 6.5, 4.5 by 10, 5 by 12, 10 by 20 cm.; square, 15 by 15 and 20 by 20 cm. They can be placed either in direct contact with the skin or with an absorbent pad thoroughly soaked in salt solution interposed. Uniform contact with the skin should be obtained at all points. The pads should be of one quarter inch thickness and may be made of felt or layers of lint. They must be soaked in strong solution. Tap water will not do because it offers too high a resistance to the current. Two tablespoonfuls of salt to a pint of water makes a solution of sufficient strength. For large sections of the body large electrodes have to be used. In order to avoid burns the current should be increased gradually until the patient feels the sensation of warmth. To elevate the temperature of the entire body the diathermy condenser couch may be used.

Gastric Function in Pulmonary Tuberculosis.—Henry K. Mohler and Elmer H. Funk (*American Journal of the Medical Sciences*, September, 1916) conclude from a study of early and advanced cases that pulmonary tuberculosis causes a definite downward progression in both the secretory function and the motility of the stomach from the very beginning of the disease. They believe that the so called "pretuberculous dyspepsias" of some writers are misnamed, and that they are in reality manifestations associated with definite tuberculous infection. They consider that hyperacidity with symptoms occurring in the early stages, described by previous writers as common, is rare; that this is true also of hyperacidity without symptoms. They do not believe that there is an irritative stage of hyperacidity in early tuberculosis, but that the gastric disorder is the result of disease of the gastric mucosa, and that there is a distinct tendency toward the formation of a definite clinical syndrome known as delayed digestion, which is indicated by more symptoms as the disease progresses. They agree with Einhorn that the swallowing of tuberculous sputum plays a highly important part in the continuation and aggravation of disordered function, and that visceroptosis and gastrectasis are no less important.

Incidence of Contagious Diseases in Military Practice.—Maurice Boigey (*Bulletin de l'Académie de médecine*, July 18, 1916), comparing the yearly incidence of various contagious diseases in an army corps of 50,000 men on a peace footing with that during the year 1915, i. e., during active (first line) service, found the number of cases of measles to be 730 during peace against 176 in 1915; scarlet fever, 295 against 122; mumps, 1050 against 422; diphtheria, seventy-six against 105, and cerebrospinal meningitis, sixteen against twenty-eight; total, 2167 against 853. The age of the soldiers ranged from eighteen to thirty-five years. Thus, in 1915, in spite of fatigue, dense massing of men, and exposure to cold, rain, and fog, the number of contagious cases was reduced almost to one third that recorded in time of peace. The extremely transmissible measles and scarlatina failed to spread as usual among the troops quartered in close promiscuity under improvised shelters. This relative immunity may be ascribed to open air life and hyperoxygenation. The longer the war continues, however, the more manifest is an inexorable natural selection in the incidence of the contagious diseases. Those with robust constitutions fail to acquire them. Repeated contact with the virus is clearly of less significance as regards transmission than is usually recognized. But one epidemic, a brief epidemic of mumps, was observed. All the facts noted forcibly demonstrated that predisposition played an important role in the incidence of contagious diseases. At the front, infectious diseases seem usually to arise, not through immediate contagion, but through sudden development of pathogenic activity in individual subjects of a ubiquitous, perhaps attenuated virus owing to predisposing conditions in these subjects.

Experimental Hematogenous Appendicitis.—N. F. Mordvinkin (*Roussky Vratch*, May 21, 1916) introduced into the circulation of rabbits staphylococci and several varieties of streptococci after subjecting the animals to the following operations: The appendix was tied at the base, leaving the arterial circulation free. The appendix was cut between two ligatures. The appendix was cut at the base, the proximal end ligated and the distal end sewn up into the peritoneum. The appendix was ligated near the base, the free end sewn up in the abdominal wound, projecting on the outside for one cm. After the wound healed the distal end was opened and the secretions from the appendix were collected. In another series the same operation was performed, except that the opening was closed as soon as the staphylococci injected into the veins were excreted in the appendix. These experiments established the fact that the appendix possesses the property to abstract from the circulation microorganisms, and discharge them into the lumen of the intestines, thus purifying the blood. As long as the lumen of the appendix remains patent, infection does not occur, but as soon as occlusion occurs and free drainage is interfered with, the staphylococci which are injected into the circulation produce suppurative appendicitis.

Vagotonus and Sympathicotonus in Scarlet Fever in Children.—W. I. Moltchanow and D. D. Lebedeff (*Roussky Vratch*, May 14, 1916) discuss the latest teachings regarding the two divisions of the nervous system—the somatic and the vegetative, the latter comprising the sympathetic and the so called autonomous nerves. Each organ supplied by the vegetative nerves receives sympathetic as well as autonomous fibres. Functionally, these groups of nerve impulses are characterized by their antagonism. Thus, if one group carries impulses which excite activity, the other transmits inhibitory impulses. For instance, in the eye the autonomous oculomotor nerve contracts the pupil while the sympathetic dilates it. In the heart the autonomous vagus slows the heart's action, while the sympathetic nerve increases it. In the stomach and intestines the vagus increases peristalsis, while the sympathetic inhibits it. The different behavior of these nerves can be demonstrated by the action of certain drugs. Thus adrenaline excites the sympathetic nerves, having no action on the autonomous. Pilocarpine, on the other hand, has no effect on the sympathetic system, but excites the autonomous nerves. Atropine paralyses the same fibres of the autonomous system as are excited by pilocarpine. As these nerves have to do with internal secretions and metabolism, their study in acute infections is of considerable interest. This can be accomplished by the pharmacological tests devised by Eppinger and Hess. The author applied the tests to ten children, varying in age from six to twelve years, during the second and third weeks of scarlet fever. The following method was employed: Twenty-four hours before the test, the patient was given fifty to 100 grams of glucose on an empty stomach, in the morning, and each portion of urine voided during the twenty-four hours was tested for the presence of sugar. If no sugar appeared an equal amount of glucose was given on the following morning, and one to one and a half hour later from 0.7 to one c. c. of adrenaline, one to 1000, administered subcutaneously in fifteen to twenty c. c. of normal salt solution. In one to three days later the pilocarpine test was applied by administering subcutaneously from 0.004 to 0.01 gram of pilocarpine. A few days later atropine was injected in doses of 0.0004 to 0.001 gram, according to age. The blood pressure and pulse were determined before and after each experiment. The effect of adrenaline was determined by the appearance of glycosuria, redness of the skin, and the state of the pupils. The pilocarpine and atropine reactions, by the salivation, perspiration, and lacrymation. In some cases Aschner's sign was looked for, namely, decrease of pulse rate on pressure on eyeball. Analysis of the results obtained by the authors shows that only one of the eight patients who received adrenaline showed a slight glycosuria. Three did not react at all, while the others showed either a rise in blood pressure or increased pulse rate, or both. All ten reacted to pilocarpine in varying degrees. All reacted to atropine, although not to the same extent. These results show that if there is an increased tonus in one division of the vegetative system there is a lowered tonus in the other. In eight of the patients a vagotonus was observed, and in one a balance of both systems. Applying these results to conditions found in scarlet fever, the authors conclude that the cardiovascular disturbances and eosinophilia are due to a vagotonus. The white dermographism which they observed in all cases they attribute to local changes in the vessel walls and the inflammatory process in the skin.

Infectious Nasopharyngeal Inflammation.—Walther Blumenthal (*Berlin. klin. Woch.*, Feb. 28, 1916) states that a common form of infection of the nasopharyngeal tissues is prevalent, but is usually unrecognized as such. It is commonly diagnosed as influenza or some other vague infection. The clinical picture of this infection comprises a sudden attack of fever in a previously normal man with great exhaustion, annoying headache in the occipital region, and no symptoms pointing to any particular organ except in some cases of dryness or itching at the back of the nose. Examination reveals nothing outside of the nasopharynx except somewhat swollen and tender glands behind the upper portion of the sternomastoid muscle. Postnasal inspection reveals a congested, inflamed mucosa which is covered with tenacious, yellowish green mucus, and an enlargement of the pharyngeal tonsil with filled lacunæ. At times, also, the posterior ends of the turbinates are seen to be swollen, but examination of the anterior portion of the nose reveals nothing. The condition is decidedly infectious, and may lead to such complications as otitis media and a temporary albuminuria or hematuria. The condition is due to a streptococcal infection, but its course is usually short—seldom over three days—and the termination is favorable. Local treatment with saline sprays and menthol inhalations, combined with the administration of salipyrin or antipyrin, is all that is required. The condition should be recognized by every practitioner.

Injuries to the Peripheral Nerves Produced by Modern Warfare.—C. Burns Craig (*American Journal of the Medical Sciences*, September, 1916) says with regard to injuries to the peripheral nerves produced by shot and shell that laceration and contusion usually may be differentiated by careful neurological examination. In some cases exposure of the nerve at the site of the injury is the only means by which exact knowledge of the nature of the injury to the nerve is obtained. Neither test of function nor electrical reaction will differentiate contusion from laceration. Patients with simple contusion recover slowly, and as a rule completely. Gunshot and shell wounds causing lacerations of nerves do not lend themselves readily to plastic operations. Because of the infection weeks and months elapse before plastic work can be undertaken. During ten months no recovery in such cases was observed.

Edematous Conditions and Infectious Disease.—Jürgens (*Berlin. klin. Woch.*, Feb. 28, 1916) has observed a number of cases of marked edema in the course of the war under a variety of conditions, and he attributes the condition to some form of infectious disease. Aside from the edema, which is often extensive, the symptoms have been those of slowly progressive weakness, with slight yellowness of the skin and pallor. Occasionally pains in the legs were observed, as well as scorbutic symptoms and severe intestinal disorders. From a close analysis of a large number of such cases, which were encountered almost exclusively in poorly nourished persons driven to hard work, he concludes that the condition is due to a dietetic deficiency and is similar to beriberi. This, he believes, is confirmed by the fact that a more liberal diet, in the sense of greater abundance of substances known to contain vitamines, has usually speedily cured the patients.

Radiography of the Bronchial Lymph Nodes.—Walker Overend and Clive Riviere (*Archives of Radiology and Electrotherapy*, August, 1916) divide the bronchial lymph nodes, anatomically, into four groups: 1. Tracheobronchial; 2, bifurcation; 3, hilum, and 4, pulmonary, and give the location of the different groups. Clinically, cases are grouped into four divisions: 1. Normal, with no physical signs; 2, with right paravertebral dullness; 3, with double paravertebral dullness; 4, showing parasternal dullness on one or both sides. In the series of cases examined radiologically every case was examined in three positions: dorsoventrally, ventrodorsally and right semilaterally The method of diagnosing the different forms of nodes is given. As the result of the examination of numerous individuals the following deductions were made. 1. That thoracic tubercle is widely distributed in children of school age in thickly populated urban districts; 2, there are notable powers of resistance which can control these processes even after extensive dissemination throughout the lung; 3. That serious chances of recrudescence exist under conditions of stress which these children must combat in adolescence and adult life; and 4. there is mutual interdependence of clinical and radiological methods of examination in complete investigation of the tuberculous thorax.

The Action of Camphor, Borneol, and Menthol on the Veins and Peripheral Bloodvessels.—N. P. Lichatcheva (*Roussky Vratch*, May 21, 1916) found by experiments on the isolated ear and heart of rabbits that camphor, borneol, and menthol, in dilution of one to 2,500 to one to 5,000, act as vasodilators. Most effect was produced by borneol, next menthol, and last camphor. The latter was found also to exert a beneficial influence on the neuromuscular mechanism of the heart, increasing its blood supply and nutrition.

Pathological Causes of Sterility.—John Osborn Polak (*Surgery, Gynecology and Obstetrics*, September, 1916) says that the result of study of sterility has shown: 1. A large number of cases of sterility applying for relief have no chance whatever of becoming pregnant, as the pathological condition is such as to make conception impossible. 2. The male is largely responsible for our poor results in treatment. 3. There is a definite chemicophysiological factor in conception, at present unexplainable, which prevents conception. 4. Operative procedures on the uterus, except amputation of the hypertrophied portion, have but slight influence on the end results in the treatment of sterility. Each case must be individualized and both contracting parties carefully studied before treatment is inaugurated.

Palpation of the Ureters through the Vagina.—A. M. Judd (*American Journal of Obstetrics*, June, 1916) asserts that, in a complete vaginal examination, palpation of the ureters is as important as palpation of the Fallopian tubes. The normal ureters are, in fact, more easily palpated than the normal tubes, and can be felt in ninety per cent. of all instances. The statement is usually made that only the short portion of the ureter in contact with the anterior vaginal vault is accessible to palpation. Judd, however, instead of palpating for the ureter in the anterior vaginal fornix, begins at the lateral fornix, using the left index finger for the left and the right index for the right ureter. The ureter is palpable above the spine of the ischium, underneath the peritoneum, before it enters the broad ligament in the course of its passage into the bladder. When normal, it is felt as a slender cord, with its convexity outward and forward, and with restricted mobility. Its size appears to be about that of an ordinary goose quill, and it is best palpated by carrying the finger above the point of its location, then slightly bending the ends of the fingers, as one might in picking the strings of a guitar, and sweeping them from above downward over the ure ter. Ureteral palpation opens an important diagnostic field. Thus, an acute ureteritis is diagnosticated by simple tenderness along its course. Chronic ureteritis and periureteritis show, in addition, thickening and a decrease of mobility depending upon the extent of the disease process around the ureter. Ureteral and renal tuberculosis yield a nodular feeling also. Calculi and gravel in the ureter can often be detected, especially when smooth or pocketed, where the wax tipped catheter fails to disclose them. Ureteral palpation in cases of pyelitis in pregnancy is especially valuable; pyelitis leads to a thickened, tender, pelvic ureter.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

Joint Meeting of the Sections in Obstetrics and Pediatrics, Held Tuesday Evening, March 28, 1916.

Dr. GEORGE W. KOSMAK in the Chair.

(*Concluded from page 526.*)

Syphilis in Mother and Infant (*Continued*).—In the past year, of twenty-seven women who were delivered of macerated fetuses at the Lying-In Hospital, nine gave a positive Wassermann reaction. Syphilis had been held responsible many times for the intra partum death of the infant, but the mechanical conditions which sometimes occurred during delivery and which caused asphyxia, would have to be excluded before syphilis could be regarded as the sole etiological factor. Boardman said that two thirds of all syphilitic children were born about the eighth month, but at the Lying-In Hospital in a series of 106 mothers with positive Wassermann reactions, there were thirty-one living babies delivered at term; this might appear to be a large proportion of syphilitic children to reach term, but some of the mothers had received antiluetic treatment during the last three months of gestation.

Only about twenty-eight per cent. of children born syphilitic survived the first year. The Wassermann reaction was valuable in making a diagnosis in a doubtful case of syphilis of the infant, four plus meaning but one thing. There had been many negative reactions on infants whose syphilitic mothers had received considerable treatment. Spirochetes might be sufficient in number and virulence to produce symptoms in the infant and at the same time not produce enough antibodies in the blood serum of the mothers to give a positive Wassermann reaction. Judging from the latter, syphilis had little or no part in the etiology of fatal anomalies. In the last two years at the Lying-In Hospital the serums of 2,049 patients were examined and sixty-four, or 3.05 per cent., gave positive Wassermann reactions. This gave a fair conception of the extent of the disease among women at the child bearing age, the majority of whom lived on the lower east side of the city. The successful results in the treatment of pregnant women, estimated by the number of children which were born with or without symptoms, depended on the amount of treatment the patient received during pregnancy and during conception. It was believed that salvarsan could be given in moderate doses, at intervals of a few days, without danger to the fetus or normal labor, but large doses were dangerous. There was considerable difference of opinion whether salvarsan given intravenously to the mother was always transmitted to the fetus. Of ten patients treated during pregnancy, five received arsenic and mercury from the second month to term; three gave birth to living babies without symptoms and with a negative Wassermann reaction; one, who was in the active secondary stage throughout her entire pregnancy, was delivered of a living baby without symptoms, but with a positive Wassermann, and one was delivered of a macerated fetus at seven months. Of the five women who received treatment from the seventh month to term, five living babies were delivered and three gave positive Wassermann reactions.

Dr. HENRY KOPLIK said that it was difficult in the presence of the enormous ground covered, to do justice to the whole subject in discussion. They could only take up points that interested them as individuals. It was astonishing how little was being done for the newborn in the modern hospitals in a great city like New York. There was much space and expensive equipment for the care of the mother, but how secondary was the consideration for the infant! He did not wish to criticize too severely, as he judged as an outsider, entering these hospitals only as a consultant. On entering a hospital of second magnitude he had seen along a wall rows of small cribs like waste baskets. There were ten infants in a room ten by fifteen feet. In another hospital there were forty infants in a single ward. In another, he found ten or twelve babies in one small room in the care of one nurse who fed and attended them without assistance. The great mortality in the newborn was in the first month of life, fully thirty per cent. of deaths in children under three months of age occurring in the first month. It was important, therefore, to give a greater place to the care of the infant in the hospital where it was born. He blushed to think how many cases of sepsis in very young infants he had been called to see. There was no excuse for much of the artificial feeding in the maternity hospitals. It was painful too how large a number of infants depended on the bottle, whereas it would seem that human milk could be obtained from other sources when the mother was unable to supply it. As to facilities for treating the newborn in the maternity hospitals of New York, they were deficient. Sepsis in the newborn, infants who had gone to a state of inanition with hemorrhage, occurred because most of these hospitals relied on primitive methods. He recalled having been summoned to see a newborn child with hemorrhage, and he had advised transfusion at once. Instead of that, subcutaneous injection of cow's serum was resorted to, and the infant did not do well. This was in a hospital of the second rank, where there were no facilities for transfusing the mother's blood to the child. He would make a plea, not only for more space for the babies so that the obstetrician might be proud of the babies' ward (which they could not be at present), and for more facilities for treatment of the newborn, particularly in emergencies, but also that pediatrists take charge solely of the children to give them the benefit of progress in modern pediatrics. He was simply calling attention to the manifest indifference to the welfare of the newborn in this great metropolitan city, where there was plenty of space and plenty of money to do what was right. In conclusion, he wished to call attention to another point in the prenatal care of the infant: Not much could be done in this direction among the poorer in

New York unless cooperation was obtained from the father who should be made to appreciate its necessity, whereupon he would aid the mother; thereby more good could be done in the prenatal care of both mother and child.

Dr. EDWIN B. CRAGIN, as an obstetrician, was glad to acknowledge obligations to the pediatrist on many occasions, but was glad also to call attention to the fact that if it were not for the skill and knowledge of the obstetrician in delivering a living baby to the pediatrist, the latter would not have any patient; therefore the pediatrist was also under obligations to the obstetrician. He had gathered an impression from the first paper that the obstetrician was apparently not considered competent to take care of the baby during the first month of its life, and it seemed to have been overlooked that the obstetrician had spent almost as much time on the study of the care of the young baby as the pediatrist. If the obstetrician watched and cared for the mother all through her pregnancy and had been studying from fifteen to eighteen hundred babies a year, he must have learned something about the care and feeding of the newborn.

He was happy that Doctor Koplik acknowledged he criticized the hospitals only as an outsider. From the inside he would have learned that the babies' care was studied and that even the waste baskets had their advantages; they provided individual beds, easily cleaned and handled, as well as air and space.

In regard to artificial feeding, many women today were unable to nurse their babies and it was often a grief to them. It was impossible at the Sloane Hospital to get enough breast milk to feed the babies on that alone. The nerve strain of modern life was shown in the lessening of the supply of breast milk; the mothers who had it believed it belonged to their own children. Breast milk could be bought, but it was expensive and it was impossible to obtain enough to feed all the newborn in the hospital whose mothers could not nurse them. At the Sloane Hospital he did not allow the nurse in the operating room to swab out the baby's mouth with gauze wrapped around the forefinger, and for some time he had not allowed the nurse to wash the baby's mouth before or after feeding. It had lately been brought to his attention that there were a few cases of mould thrush, and for the last month the mouth of the child had been gently cleansed once a day with sterile cotton and boric acid solution. They should have the mothers attend ante partum clinics and they should be surrounded with all the prenatal care possible. There should be social service workers in all the hospitals. A Wassermann should be taken in every case that applied to the hospital for obstetrical care, as it worked in the interest of the mother, the baby, and the hospital; the latter was protected against responsibility, which had been heavy in those cases where a syphilitic baby, apparently healthy at birth, had been put out to nurse and had infected the foster mother. Having followed the mother carefully through her pregnancy and the puerperium, it should then be their duty to place the mother and her baby in touch with the proper welfare society or pediatrist, so that their subsequent care might be assured.

Stated Meeting Held April 6, 1916.

The President, Dr. WALTER B. JAMES, in the Chair.

The Influence of Alcohol on Man, with Special Reference to Psychological Effects.[1]—Dr. FRANCIS G. BENEDICT, director of the Boston Nutrition Laboratory of the Carnegie Institution, said that in accordance with its widely distributed "tentative plan" the nutrition laboratory of the Carnegie Institution had organized and initiated an exhaustive experimental study of the physiological consequences of the ingestion of small doses of ethyl alcohol in man. The first year's work under the psychological part of that plan was devoted to an investigation of the effects of alcohol on a selected group of interrelated processes covering the fundamental neutral activities at various levels of the cerebrospinal system, from the simplest reflexes of the lumbar cord to the most complex cortical arcs that they could accurately measure by available laboratory technic. The selection of the particular group of neuromuscular processes for measurement was determined by the following experimental demands: 1. The systematic demand for coordinate data covering as many as possible of the fundamental psychophysiological operation. 2. The interpretative demand for the least possible inclusion of unknown and uncontrolled factors. 3. The practical demand for natural reaction forms which would be comparable in a large number of individuals without special practice, and would show relatively little practice effect as a result of the experimental repetition. 4. The technical demand for trustworthy quantitative methods of stimulation and registration. Of the simple arcs which were available for experimentation, the patellar reflex and the protective lid reflex were chosen, chiefly because of their similar latency and the accuracy of their modern technic. Their measurements of these reflexes included data concerning their latency, the extent of the muscle contraction, and the relative duration of the refractory phase. Of the more complex cortical arcs the following were selected: 1. Eye reactions to sudden peripheral stimuli, a thorough practised phase of each individual's spatial adjustment; 2, speech reactions to visual word stimuli; and, 3, free associations. The last two were characteristic phases of the individual's adjustment to his social environment. The fundamental perservation tendency was measured by the partial memorization of series of words. Sensory changes were indicated by Martin's faradic threshold measurements. Morot coordination was studied in the velocity and accuracy of eye movements, and in the reciprocal innervation of the antagonistic muscles of the middle finger. Finally, pulse records (chiefly electrocardiograms from body leads) were taken either continuously or at homologous points in the various experimental processes. The subjects consisted of two groups: A main group of college graduates, who were moderate users of alcohol, and a smaller group of out patients in the Psychopathic Hospital who had been under treatment for delirium tremens. Normal base lines in all

[1] Abstracted from January issue of *Nat. Acad. Sciences.*

cases included two normal experimental days for each subject and for each kind of experiment. One normal day came before and one after the experimental days on which alcohol was administered. In addition a "normal of the day" was recorded for each experimental process on the days in which alcohol was given. Two alcohol doses were used, one containing approximately thirty c. c. and the other forty-five c. c. of absolute alcohol. All the measurements showed more or less rhythmic variations. In their statistical theory they assumed that, given a sufficiently large number of measurements, the normal rhythmic and arrhythmic variations would tend to compensate each other, leaving the average experimentally conditioned change relatively unaffected. In their data these average results showed two particularly significant marks of reliability: 1. Similar processes were similarly affected and in similar degree; 2, in general the larger dose of alcohol showed the greater experimental effect. The effect of alcohol was calculated in all cases by comparing the differences between the "normals of the day" and subsequent periods on the normal and on the alcohol days. The greatest percentage effect was found in the reflexes. In the patellar reflex alcohol increased the latent time ten per cent., while it decreased the amount of quadriceps thickening forty-six per cent. In the protective lid reflex it increased the latent time seven per cent., while it decreased the extent of lid movement nineteen per cent. It increased the latent time of the eye reactions five per cent. and that of the speech reactions three per cent. Memory and the free associations were only slightly affected. Sensitivity to faradic stimulation decreased fourteen per cent. after alcohol. The number of finger movements decreased nine per cent. and the velocity of the eye movements decreased eleven per cent. as a consequence of the ingestion of alcohol. Quite in contrast to the general depression of the neuromuscular processes at all levels of the cerebrospinal system was the effect of alcohol on the pulse rate. Under all experimental conditions alcohol produced a relative acceleration of the pulse. In only a few cases with a large dose did this relative acceleration become a positive acceleration, so that the pulse rate in the periods subsequent to the ingestion of alcohol was faster than during the normal of the day: but in practically every instance alcohol prevented the regular pulse rate retardation that accompanied the successive periods of mental and physical work on normal days. This relative acceleration was approximately three per cent. While this effect was intrinsically small, its regularity, the large number of records, and its concomitant variation with the size of the dose gave the results a high degree of probability. The effort to determine which of the antagonistic heart regulating mechanisms was responsible for the relative acceleration, demanded an analysis of the pulse data. A comparison of the relative changes in the duration of systole and diastole (method of Hunt) led to a thoroughgoing consideration of the variations in the pulse cycles during the different experiments. The records showed a consistent tendency of alcohol to decrease the mean variations amounting to an average of nineteen per cent. Since the rhythmic and arrhythmic pulse changes within the limits of their twelve second records could not have been conditioned by the relatively slow acting accelerator, it seemed necessary to regard the decrease of the mean variation after alcohol as caused by a decreased responsiveness to the inhibitor. There was some evidence in the records that this paralysis of the inhibitor was not an exclusive effect, and it was probable that various natural and experimental conditions might be found which would shift the preponderance of paralysis to the accelerating mechanism. The small amount of change, its purely relative character, and the probability that both regulating mechanisms were affected, doubtless give the conditions for the confusion of the scientific traditions concerning the effect of alcohol on the pulse rate. In conjunction with the pulse acceleration, the general neuromuscular depression might be regarded as presumptive evidence of the effect of alcohol on organic efficiency. In none of their data was there any indication of a pure facilitation effect of alcohol. Contrary to the theory of Kraepelin, they not only found no facilitation of the motor processes, but the depression of the simplest forms in the finger and eye movements seemed to be one of the most characteristic effects of alcohol. Indeed it was exactly these effects that correlated most closely with the average of all the effects for the several subjects. Practically it seemed to follow that these processes might serve as a readily accessible indicator of individual susceptibility to alcohol. Theoretically it seemed to follow that the effect on the motor coordinations indicated a central tendency of alcohol.

Professor C. E. A. Winslow, of Yale University, emphasized the great difficulty in discussing this subject from a detached and scientific viewpoint. It was hard to consider the evidence on its merits, since each new fact was apt to fit into and be modified by a preconceived picture, of which the centre was either the Demon Rum or the genial god, Dionysos. Their treatment of alcohol as a habit forming drug was complicated by the fact that in this case there were not only the confirmed addicts to be considered, but also those who gave way only occasionally to excess and the steady, moderate drinkers. If there were signs of opium parlors on every street corner, or if hypodermics were passed at the close of dinner parties, their view of these drugs would be similarly complicated by a century old atmosphere of social respectability, although of course the danger of habit formation would be quantitatively greater than in the case of alcohol. They must freely grant that alcohol was technically a food, and that it might be and was oxidized in the body. They might grant that in moderate amounts it was a source of pleasurable indulgence. The question was whether this food value and this indulgence were not too dearly bought.

It was unnecessary to emphasize to physicians the relation of steady drinking to diseases of the liver and kidneys and to mental diseases, and its unfavorable influence upon the prognosis of such infections as pneumonia. Alcohol in large and continuous doses produced more or less serious pathological effects, in some instances constituting a principal contributory cause of death; and the extent of the dan-

ger varied widely with individual predispositions. There were also to be considered the many secondary effects of alcohol in connection with the causes of disease and death. Alcohol played a large part in automobile accidents and accidents occurring in factories. The relation of alcoholism to venereal disease was far reaching and sinister. The taking of alcohol with meals promoted overeating and tended to overload the alimentary canal with food which would putrefy and cause autointoxication.

The net effect of alcohol upon health had been approximately measured in a number of statistical studies by English and Scottish life insurance companies and more recently in the admirable medico-actuarial investigation conducted by Arthur Hunter. This study showed a mortality eighty-six per cent. in excess of the normal among steady users of two ounces or more alcohol a day, seventy-four per cent. in excess of the normal among those who had committed alcoholic excesses within two years, thirty-two to thirty-five per cent. in excess of the normal among reformed persons of formerly intemperate habits, and eighteen per cent. in excess of the normal among moderate, steady drinkers (lower limit defined as two glasses of beer or one glass of whiskey a day). These results could not be considered extravagant when it was remembered that the same study showed an excess mortality of thirteen per cent. for persons showing albumin in the urine, twenty per cent. for those who had suffered from acute articular rheumatism within two years, and seventy-two per cent. for those who had had an attack of gout within ten years.

Passing from actual damage to the question of lowered efficiency, they must take into account the laboratory studies of Kraepelin, Vogt, Aschaffenburg, and others, and the remarkably clear and convincing investigations just reported by Doctor Benedict. There were persons who had lived long lives and done good work, yet who had consumed enormous amounts of alcohol. But if a responsible man had anything important to do, he did not take alcohol before doing it. A surgeon about to perform a delicate operation did not take alcohol before entering the operating room. No man about to undertake severe, exact mental work would take a drink of whiskey beforehand. When they wanted cool, concentrated energy, they laid drink aside.

The same thing had been most clearly indicated by the changed attitude of European nations toward alcohol during the war. As Russia, France, and England reached the point where they needed a maximum of efficiency, they faced this as one of their greatest obstacles. On March 9th last, David Lloyd George said of the alcohol problem, that it would be so much better to settle the question by general consent. If they did, the war, horrible as it was, would have paid for itself. There were many things which he hoped they could accomplish through this war. There were many changes at home, changes in the outlook in the nation, changes in its temper, changes in its attitude of mind, changes in its industries; but this would be the greatest and most beneficent change of all if they succeeded in carrying it through. If they could possibly convince the nation that success in the great task which it had undertaken depended very largely upon removing this drag on its efficiency, then he felt confident that at the end of the war, however successful they might be in a military sense, they should regard this as the greatest triumph of all.

No one method of fighting against alcohol was approved; the question of the need for restriction was a sufficiently thorny one without entering into the methods. There were grave criticisms of many of the methods that had been proposed. The best way to restrict the use of alcohol was a problem in itself, but from a standpoint of public health and efficiency that way should be found. Public health departments were not limiting themselves to the prevention of specific diseases and of death, but were developing their work along hygienic lines.

(To be concluded.)

Letters to the Editors

AUTOINOCULATION IN POLIOMYELITIS.

BROOKLYN, NEW YORK, *September 5, 1916.*

To the Editors:

I read with much interest in the *New York Times* for September 2nd, the review of Doctor Meltzer's letter which appeared in the NEW YORK MEDICAL JOURNAL of the same date. As I am entirely responsible, so far as I know, for the application of autoinoculation in the treatment of poliomyelitis, it seems in order for me to reply briefly to Doctor Meltzer's criticism.

In the *Archives of Pediatrics* for October, 1915, I published the report of the first case that I had treated in this way. Doctor Meltzer gratifies me by his admission that the method is based upon scientific principles in so far as it might stimulate the formation of antibodies and thus have a curative effect in some instances. He then cites his reasons for considering the method unsafe on the ground that there is danger of increasing the extent of the infection by the introduction of more virus. Although he asserts that he has tabulated the previous experiments which render this process dangerous, he has failed to mention the fact that the experimenters who endeavored to inoculate monkeys by intramuscular injection have reported that it is difficult and in some instances impossible to produce a general infection in this way. Doctor Meltzer also assumes that a larger number of organisms are being introduced into the system than were there previous to the treatment. As the treatment consists in drawing off from fifteen to sixty, seventy, or even a larger number of c. c. of spinal fluid and reinjecting into the muscular tissues from 0.5 to two or three c. c. of fluid, this argument appears to be baseless. It is true that this method has not been tried out on monkeys, and it is also true that experimentation of this nature on human beings is under ordinary circumstances inadmissible. The first cases tried, however, were those in which there appeared to be no hope of recovery, and in which consent was freely given by the parents after the method had been explained. In all these cases there was absolutely no local reaction and no indication that any harm had been done. These observations could be much more readily made in human beings than in monkeys, and under the circumstances I consider the trial justifiable.

In a number of instances the treatment was followed by marked improvement, reduction in temperature, and partial return to consciousness. Under the circumstances, the next step in using the treatment in a more general way also seems to be justified, and I have used it during the entire epidemic in my consultation work. As Doctor Meltzer states, the procedure is so simple that I am sure it has been adopted by a number of other physicians. I have had no unfavorable reports of its use and no occasion to think that it was in any way harmful in any of my cases. It has been used extensively in the Kingston Avenue Hospital, but by no means exclusively.

Early in July, I had a long conference with Doctor Meltzer in his office in regard to treatment, and we were

very glad to adopt his suggestions at the Kingston Avenue Hospital for the use of oxygen and adrenaline. In fact, I secured at my own expense adrenaline in ampoules in order that there might be no danger of infection in this method of treatment. At the same time we made use of the small amount of convalescent serum that we were able to obtain, and at the suggestion of Doctor Sophian, normal horse serum was used to a considerable extent.

To all those persons, particularly newspaper men, who have requested a statement in regard to treatment, I have replied from the beginning that nothing would be known about the treatment of the disease for at least three months. By that time, I presume that some of us will be ready to express our views.

In a footnote to his letter, Doctor Meltzer states that he has been informed that the autoinoculation treatment is prohibited in health department hospitals. I have not received any such information. The treatment is not being used at present at Kingston Avenue because it was given a fair trial and because convalescent serum is more readily obtainable now than previously, and I consider that, at present, the treatment should be thoroughly tried out.

Many of the families in which autoinoculation has been used, and many of the physicians who have used it, are enthusiastic about the results. After seeing so many hundreds of cases with their varying outcome, good, bad, and indifferent, regardless of treatment of various kinds and no treatment at all, I am personally very skeptical of the real value of autoinoculation, convalescent serum, normal horse serum, or adrenaline. I have felt from the first that the intraspinal injection of convalescent serum was based more or less upon a false conception of the disease, and that considering the lines of infection and the possible late appearance of the virus in the spinal fluid, the convalescent serum would be of greater benefit if introduced intravenously, but this is merely a theory on my part. It would be a mistake to decide that all preparations of antibody serums would be useless; even if, as now appears to be the case, the convalescent serum has little or no value. An earnest effort should be made in the laboratories to find some method of producing a highly active serum in some of the lower animals which will contain the antibodies in sufficiently concentrated form to be of real value.

Louis C. Ager, M. D.

POLIOMYELITIS AND GRIPPE.

Carmel, N. Y., *August 28, 1916.*

To the Editors:

Permit me the courtesy of your columns to call attention to the fact that in the phase of disease known as anterior poliomyelitis we are witnessing simply a localization of that protean plague, influenza. Instead of localizing in the lungs or stomach or intestines or spleen or liver or kidneys or other parts of the human anatomy as it sees fit to do at any and all times in its peregrinations through the body, this year it is localizing in the spinal cord and its membranes.

The greatest mistake that the medical profession has ever made, in my opinion, consists in the remarkable lack of appreciation of the stupendous possibilities ever present in that most remarkable of all constitutional diseases that we speak of so lightly as grippe. In the humble opinion of the writer the study of this worldwide disease is the most important among all the studies in epidemiology. Any and all parts of the body are subjected from time to time to its visitations, these showing themselves always and ever in the form of congestions and inflammations. No matter what particular organ or organs become affected, the basic, fundamental, initiative condition is congestion followed, if not relieved, by inflammation and its sequelæ.

Disturbances in the functions of the organs involved follow as a matter of course, and these, on account of the widely divergent gyrations of the disease, set up widely divergent sets of symptoms, one set differing from another to such an extent at times as to cause the observer to think that he is dealing with an entirely different disease, whereas, in reality, he is witnessing progressions or phases of the same old plague, influenza.

That is how the present epidemic of (so called) infantile paralysis is being considered as a separate disease, distinct from all others, when, as a matter of fact, it is a localization of the influenza disturbance in the spinal cord and its membranes. The basic, fundamental condition present in this phase of the grippe is identically the same as that found in any other part of the body when such other part is attacked. This is the condition known as congestion followed by inflammation and its sequelæ. The only variation is in the symptoms, and these, naturally, arise from the disturbances brought about in the functions of the organs affected. In the particular case under discussion the functions of the spinal cord are interfered with to a greater or less extent, hence the paralytic or semiparalytic conditions witnessed.

There is no doubt that there do occur at times sporadic cases of congestive and inflammatory conditions of portions of the spinal cord and its membranes—entirely local conditions—and these are justly entitled to rank as separate, individual instances of a local disease, but when we find, as in the present instance, as well as in many previous instances, outbreaks occurring of a widespread nature with the symptoms of spinal cord disturbance interlaced with symptoms of congestion and inflammation of other organs throughout the body, then indeed must we look for the presence in the system of some constitutional disease of a very general character and having some seemingly selective action upon the spinal cord and its membranes.

Our search for such a disease begins and ends with the greatest of all constitutional diseases, influenza. The whole history of this disease points to a universal diffusion throughout the entire body; hence the spinal cord and its membranes cannot hope to escape involvement in the course of the long drawn out epidemics. One of the principal pathological conditions found in this phase of disease is a hemorrhagic myelitis. "The changes in the cord consist in hemorrhages, for the most part punctate, most marked in the anterior part of the gray matter and of a very extensive perivascular infiltration." (Robert W. Lovett, Harvard University.)

Now compare this pathological condition with that occurring in influenza. Here we find hemorrhagic conditions occurring in various parts of the body, dependent seemingly upon a certain congestive condition of the blood. These hemorrhagic conditions vary as to the organ or organs affected in different patients. They also vary both as to incidence and severity, in different epidemics. In certain epidemics uterine hemorrhages have prevailed to such an extent as to cause considerable numbers of women who were pregnant to abort. Raising of blood in patients suffering from grippe has been at times an extraordinarily common symptom. Cystic and rectal hemorrhages have also at times been prominent features of the grippe.

Putting this and that together, we find a remarkable similarity existing at the very foundation of the pathological conditions of both influenza and acute anterior poliomyelitis. The instant we leave the foundation, of course, the picture changes. The difference in functions of the parts hemorrhagically inclined takes us off in different directions, the divergences varying more or less just as the amount of hemorrhagic or congestive disturbance in the different organs varies. The foundation or essential conditions are identical.

Congestions (with their sequelæ of hemorrhages, either punctate or diffused), followed by inflammatory conditions with their sequelæ of inflammatory products) are identically the same in both influenza and infantile paralysis. Hence, as the less must perforce be contained in the greater, there is but one deduction to be made and that is that acute anterior poliomyelitis is but part and parcel of the greatest congestive disease known to science.

Influenza congestion is at the basis of a vast number of disturbances of various organs, the disturbed functions of which when grouped together form pictures so distinctive that the mistake of confounding them as separate, individual diseases is readily excusable. The congestion that occurs in the spinal cord and its membranes is not one whit different from the congestion that occurs in the conjunctivæ or in the bronchial tubes or in the lungs or in the stomach or, in fact, in any other organ of the body. The only difference, as stated before, lies in the variation of symptoms, and these depend upon the interferences exerted upon the various functions of the organs by the congestion and inflammation.

The bacteriologists, in stating infantile paralysis to be a separate disease from all others, are making the mistake of their lives.

There is a progressiveness in disease conditions that can

be positively proved. The "checker board" arrangement of diseases as laid down by the bacteriologists is untenable.

Given a certain amount of virus, whether we regard this "virus" as imported from without by medium of germs, or purely and simply as "virus," we have a primary stage of disease established. Given a larger quantity or more concentrated, we have a secondary form of disease established. Given a still larger quantity, we have the tertiary stages of disease manifested. That is what we are experiencing in this present epidemic of infantile paralysis—a certain gradation of disease. The sooner the medical profession begins to realize that there are primary, secondary, tertiary, quarternary, etc., stages of these epidemic diseases, the better.

J. D. HARRIGAN, M. D.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

A Textbook of Practical Gynecology. For Practitioners and Students. By D. TOD GILLIAM, M. D., Emeritus Professor of Gynecology in Ohio State University College of Medicine, etc., and EARL M. GILLIAM, M. D., Professor of Diseases of Women in the Ohio State University College of Medicine, Columbus, Ohio, etc. Fifth Revised Edition. Illustrated with 352 Engravings, a Colored Frontispiece, and 13 Full Page Halftone Plates. Philadelphia: F. A. Davis Company, 1916. Pp. xvi-681. (Price, $5.00.)

In this well known textbook of gynecology, it is the avowed policy of the author to present a plain connected narrative of the subjects under discussion rather than to follow strictly scientific methods of classification and arrangement. This plan has been pursued with a considerable measure of success, and the result is a comprehensive but eminently practical presentation of the matters dealt with. Bibliographic references have been omitted and few citations from authorities are made. Moreover, the book is divided into a number of chapters of as nearly uniform length as possible to correspond to the number of lectures and recitations usually allotted to the subject during a collegiate term. That the work within a few years has gone through five editions is sufficient evidence of its intrinsic value and the best testimony to its popularity. This edition has been thoroughly revised and brought up to date and may be conscientiously recommended to practitioners and students.

A Manual of Surgical Anatomy. By LEWIS BEESLY, F. R. C. S. (Edin.), Assistant Surgeon, Chalmers' Hospital, Edinburgh, Lecturer on Surgery and Operative Surgery, Edinburgh School of Medicine for Women, etc., and T. B. JOHNSTON, M. B., Ch. B., Lecturer and Demonstrator of Anatomy, University College, London, Lately Lecturer and Demonstrator of Anatomy, Edinburgh University, etc. New York: William Wood & Co., 1916. Pp. xiv-557. (Price, $3.75.)

The object of the authors in presenting a new manual of surgical anatomy is to correlate the subject more intimately with dissecting room work. The tendency of the student being to make use chiefly of works on regional anatomy which give them anatomical facts only, it has seemed desirable to the authors to put in the hands of the dissector a work dealing with the surgical application of the anatomical facts. They are peculiarly fitted for this work from their experience in teaching both regional and surgical anatomy. Surgical technic has been excluded as far as possible, the chief emphasis being laid upon the anatomy of the operations.

The book, therefore, fills a distinct place among textbooks by bringing the practical study of anatomy into closer relation with practical surgery and by reviewing anatomical facts in the study of operative surgery. The work has been well done, the descriptions being accurate and clear and all that is unessential being excluded. The surgical anatomy of joints has received special attention, and these sections will be valuable in connection with the surgery of joint infections, notably tuberculosis.

Interclinical Notes

In the department of Common Welfare of the *Survey* for August 5th—the so called new once a month edition—there was a spirited description of the disorder incident to the attempted quarantine of infantile paralysis. In nine weeks, we are reminded, there were 3,964 cases and 841 deaths.

* * *

Those of our readers who have been worrying about the abbreviation of ten commandments proposed by the Episcopal Church, may have their minds set at rest by a perusal of the *Outlook* for September 13th, wherein it is explained that the church is merely going back to the original form of the decalogue. In the short form we find that the commandments retain their punch, while being as easily summed up as the longer form in the Golden Rule.

* * *

In *Leslie's* for September 7th, an editorial paragraph on The Music of the Disc is immediately preceded by one entitled, Breaking Records. We will yield on other points, if owners of talking machines will equip them with some automatic device to prevent their playing dance music between the hours of midnight and six a. m. In music our personal preference is for compositions played by orchestras of some 110 pieces, and records of such performances seem impossible to obtain.

* * *

The Dark Tower, by Phyllis Bottome, the remarkable serial whose beginning in the August *Century* impressed us so favorably, continues in the September issue of that journal to be absorbing. The hero and heroine seem now to be involved in a hopeless tangle that only death can solve. William Dean Howells's The Leatherwood God is in its sixth installment; it is a masterly production of the mature genius of its author. The other stories are short ones. The illustrations are beautiful, as always, and include a wood engraving by Timothy Cole of a masterpiece from the Louvre.

* * *

The editor of the *Nurse* is some hustler when circumstances demand it; witness in the September issue a paper on Infantile Paralysis, by Dr. John B. Huber. Other medical contributors to this sightly and entertaining magazine are Dr. Franklin W. Barrows, who writes on the Binet Test; Dr. James Frederick Rogers, who discusses the Nurse in the Public Schools; Dr. Leonard Keene Hirshberg, who considers Bites and Stings; Dr. Anne E. Perkins, who advises the Nurse with the Mental Patient. The banana is cited before the bar of professional opinion as an article of diet and comes through the test with colors flying, although we cannot help thinking that its photographs flatter it somewhat.

* * *

Marian Bonsall Davis writes to *Leslie's* for September 7th of how supplies are distributed to the French military hospitals. She says, among other things: "The sister superior—the hospital, like so many, is run by sisters—showed us through the wards. They welcome any one from the Fund as if visitors from heaven. You feel guilty to be accepting such a wealth of gratitude vicariously. Some of the beds were pulled out into the garden. In a tiny court they have set up a game something like croquet. Games are life savers to French convalescents. The little nun who has the *pharmacie* in charge explained some of her makeshifts. And the pretty one who led us kept up a running fire of French that ran so fast it left us quite distanced. Two of the men patients were being visited by their wives, and those four were so happy that their wounds were less a bane than a blessing. The sister superior came out to the gate to speed us on our way with renewed gratitude. The crippled man who kept the gate, having become aware of the object of our visit, almost bowed himself into new dislocations as we passed out. Our last glimpse was of the surgeon hurrying the opening of the bale and the unpacking of the *pansements*—the dressings. If you could only realize the pitiable need for cotton, dressings, gauze for wounds. You have put your hands in your pockets so many times. But the desperation grows greater. And these wonderful French—how they shoulder the burden. Never a whimper. But the war goes on and on."

Meetings of Local Medical Societies

MONDAY, *September 18th.*—Elmira Clinical Society; Psychiatric Society of Ward's Island.

TUESDAY, *September 19th.*—Tompkins County Medical Society; Tri-Professional Medical Society of New York (annual); Binghamton Academy of Medicine (annual); Syracuse Academy of Medicine; Ogdensburg Medical Association (annual); Oswego Academy of Medicine; Medical Society of the County of Westchester.

WEDNESDAY, *September 20th.*—Medicolegal Society, New York; Buffalo Medical Club; Bronx County Medical Society.

THURSDAY, *September 21st.*—Auburn City Medical Society; Geneva Medical Society; Æsculapian Club of Buffalo; New York Celtic Medical Society.

FRIDAY, *September 22nd.*—Society of New York German Physicians; Manhattan Medical Society; Italian Medical Society of New York.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 6, 1916:

ANDERSON, T. B. H., Assistant Surgeon. Granted ten days' leave of absence from September 7, 1916.

ASHFORD, F. A., Passed Assistant Surgeon. Granted one month's leave of absence from September 5, 1916.

BILLINGS, W. C., Surgeon. Bureau letter of August 4, 1916, amended to grant one month's leave of absence from August 22, 1916.

ESKEY, C. R., Assistant Surgeon. Relieved from duty at Detroit, Mich., and directed to proceed to Chicago, Ill., for duty in the Marine Hospital.

FOSTER, M. H., Surgeon. Directed to proceed to Philadelphia, Pa., for duty in connection with the interstate spread of poliomyelitis.

HUGHES, T. E., Assistant Surgeon. Relieved from duty at New York city and directed to proceed to Philadelphia, Pa., for duty in the prevention of the interstate spread of poliomyelitis.

HURLEY, J. R., Passed Assistant Surgeon. Relieved from duty at New York city and directed to proceed to Philadelphia, Pa., for duty in the prevention of the interstate spread of poliomyelitis.

LEAKE, J. P., Passed Assistant Surgeon. Directed to proceed to The Plains, Va., and other places in the vicinity of the District of Columbia, to investigate sporadic cases of poliomyelitis and obtain material for laboratory use.

LOMBARD, M. S., Assistant Surgeon. Relieved from duty at New York city and directed to proceed to Philadelphia, Pa., for duty in the prevention of the interstate spread of poliomyelitis.

SCHWARTZ, LOUIS, Passed Assistant Surgeon. Relieved from duty at New York city and directed to proceed to Philadelphia, Pa., for duty in the prevention of the interstate spread of poliomyelitis.

STONER, GEORGE W., Senior Surgeon. Granted four days' leave of absence from August 29, 1916, under paragraph 193, Service Regulations.

SWEET, E. A., Surgeon. Granted eight days' leave of absence on account of sickness from August 15, 1916.

WELLS, W. F., Sanitary Chemist. Directed to proceed to such places as Surgeon H. S. Cumming may direct, for duty in investigations of coastal waters.

WICKS, H. W., Surgeon. Granted ten days' leave of absence on account of sickness, from August 10, 1916.

YOUNG, G. B., Surgeon. Detailed to attend a meeting of the Buchanan County Medical Society at St. Joseph, Mo., August 30, 1916.

Boards Convened.

Boards of commissioned medical officers convened for the purpose of making physical examinations and conducting the mental examination of candidates for appointment as assistant surgeons, September 18, 1916, as follows: Philadelphia: Detail for the board, Senior Surgeon Fairfax Irwin, chairman; Surgeon H. McG. Robertson, recorder. San Francisco: Detail for the board, Senior Surgeon L. L. Williams, chairman; Assistant Surgeon D. S. Baughman, recorder. Ellis Island, N. Y.: Detail for the board, Senior Surgeon J. C. Perry, chairman; Passed Assistant Surgeon E. H. Mullan, recorder. Chicago: Detail for the board, Surgeon J. O. Cobb, chairman; Assistant Surgeon R. R. Spencer, recorder. Galveston, Tex.: Detail for the board, Surgeon L. P. H. Bahrenburg, chairman; Surgeon R. L. Wilson, recorder. Seattle, Wash.: Detail for the board, Surgeon John S. Boggess, chairman; Passed Assistant Surgeon E. Krulish, recorder. New Orleans, La.: Detail for the board, Passed Assistant Surgeon Friench Simpson, chairman; Assistant Surgeon S. L. Christian, recorder. Chelsea, Mass.: Detail for the board, Passed Assistant Surgeon W. M. Bryan, chairman; Assistant Surgeon M. V. Safford, recorder.

Births, Marriages, and Deaths

Married.

FOUGHT-DONOHUE.—In Philadelphia, Pa., on Thursday, June 22nd, Dr. E. N. Fought and Miss Edythe C. Donohue.

GREENAWAY-TURNER.—In Ridgetop, Tenn., on Sunday, August 13th, Dr. H. Greenaway and Miss Louise Turner.

WARD-MERCHANT.—In Binghamton, N. Y., on Wednesday, August 30th, Dr. Charles Austin Ward and Mrs. Hattie Westcott Merchant.

Died.

ABBOTT.—In Lawrence, on Friday, September 1st, Dr. Stephen W. Abbott.

BARUCH.—In New York, on Tuesday, September 5th, Dr. Solomon Baruch, aged sixty-one years.

BEDARD.—In Norway, Me., on Tuesday, August 29th, Dr. Prudent Bedard, aged sixty-three years.

BROWN.—In Billings, Mont., on Monday, August 28th, Dr. Marcus F. Brown, aged thirty-five years.

CARLON.—In West Hartford, Conn., on Thursday, August 31st, Dr. Philip P. Carlon, aged fifty-four years.

CATHELL.—In Baltimore, Md., on Tuesday, August 29th, Dr. William T. Cathell, aged fifty-one years.

CHAGNON.—In Willimantic, Conn., on Tuesday, August 29th, Dr. Joseph S. Chagnon, aged fifty-seven years.

CLARK.—In Colorado Springs, Col., on Tuesday, August 29th, Dr. Franklin A. Clark, aged fifty-four years.

COOK.—In Indianapolis, Ind., on Thursday, August 31st, Dr. George Jameson Cook, aged seventy-two years.

DUER.—In Odessa, Del., on Wednesday, September 6th, Dr. Edward L. Duer, aged eighty years.

GIESY.—In Aurora, Ore., on Friday, August 25th, Dr. Martin Giesy, aged eighty-two years.

HALLOCK.—In Pittsburgh, Pa., on Monday, September 4th, Dr. William Ewing Hallock, aged sixty-seven years.

HART.—In Bethel, Conn., on Tuesday, August 29th, Dr. Charles R. Hart, aged seventy-nine years.

LEWINSKI.—In New York, on Friday, September 1st, Dr. Michael Lewinski, aged fifty-four years.

MERROW.—In Utica, N. Y., on Monday, August 28th, Dr. John G. Merrow.

PARISEAU.—In Springfield, Mass., on Friday, September 1st, Dr. William P. Pariseau, of Ware, Mass., aged thirty-seven years.

PEARCE.—In Claussen, S. C., on Tuesday, August 29th, Dr. James F. Pearce, aged eighty-one years.

PECK.—In Philadelphia, Pa., on Tuesday, September 5th, Dr. Earl C. Peck, aged twenty-four years.

REYNOLDS.—In New York, on Thursday, September 7th, Dr. Samuel Moore Reynolds, aged seventy-four years.

SCHMITZ.—In Wauwatosa, Wisconsin, on Wednesday, August 30th, Edward A. Schmitz, aged fifty-five years.

TRUE.—In Kansas City, Mo., on Thursday, August 31st, Dr. George P. True, aged sixty-six years.

VON EZDORF.—In Lincolnton, N. C., on Friday, September 8th, Dr. Rudolph H. Von Ezdorf, of the United States Public Health Service, aged forty-three years.

WHITEHEAD.—In Lovingston, Va., on Wednesday, September 6th, Dr. John B. Whitehead, aged seventy-three years.

THE PSYCHOLOGY OF DISEASES OF THE RESPIRATORY TRACT.*

BY G. HUDSON-MAKUEN, M. D.,
Philadelphia.

The chief function of the physician, whether he is a general practitioner or specialist, is to conserve and prolong human life, and yet, notwithstanding our recent much vaunted progress in what we are pleased to call scientific medicine, it appears that the average duration of human life is scarcely greater today than it was in the days of our forebears.

This does not indicate that our progress in medicine, when put to the supreme test, has been altogether fanciful, but it does suggest that something may be wrong and that some of the cogs in our progressive medical machinery may be slipping and in need of adjustment, and if further evidence of a loss of power should be desired, we have but to look to the persistency and even increase in medical quackery. Never was there a time, perhaps, in the history of the world when 'pathies and cults in medical practice were so numerous as they are today, and the fault, it seems to me, is not in our stars but in ourselves, not that we are underlings, but that we are unmindful of certain important facts in connection with our preparation for medical work and our prosecution of it.

Without appearing to be too dogmatic and personalistic, I shall try to point out to you on this occasion wherein we, as specialists in the practice of medicine, are, in a measure, failing to live up to our highest opportunities and possibilities, and to suggest ways and means by which we may increase our usefulness. I desire to emphasize two points: First, the importance of a full recognition of the interdependence of specialties in medicine: and, second, the broad general principles which should underly all specialism in medicine. While these two propositions are to some extent interrelated, I speak of them separately, in order to give each the emphasis which it deserves.

When the practice of medicine began to divide itself into so called specialties, the question first to arise in the minds of all was, "To what extent must general medicine be practised before the physician should enter upon his chosen specialty?" In other words, the necessity for a more or less thorough knowledge of general medicine was recognized from the beginning, but that some knowledge of the various specialties themselves is desirable is a conclusion that has been of slower development.

The throat specialist must be a nose specialist and and an ear specialist and to some extent at least an eye specialist, if he would be a throat specialist in the highest sense of the term, and that he can be a better throat specialist if he is to some extent a pediatrist and even gynecologist and if he has had some experience in general surgery is becoming more and more apparent, but the specialties upon which laryngology chiefly depends for its future progress and development are those of psychology and its related branch of medicine, neurology.

I have, therefore, chosen for my subject on this occasion the psychology of diseases of the respiratory tract. First of all, let it be understood that respiratory diseases have a psychology which is peculiarly their own, as witness, for example, the psychic differences between pulmonary tuberculosis and gastrointestinal diseases, the former being characterized by marked optimism and hopefulness, and the latter by extreme pessimism or mental depression.

The peripheral mechanisms of respiration and vocalization are so closely related to their corresponding central mechanisms, that it is often quite impossible to tell during their united action where the one begins and the other ends, and it is now generally conceded that the greatest improvement in artistic and effective respiration, vocalization, and even articulation is accomplished only when their corresponding central mechanisms, coupled with the higher intellectual centres of the brain, have full rein and are in complete command.

In other words, these psychophysical processes, so vital to health as well as to artistic voice and speech production, are rather more mental than physical, and this predominance of the mental activities over the physical or bodily activities is not confined alone to the development of respiratory and laryngeal functions, but exists also to a marked degree in the various disorders of these functions.

There is no such thing as a purely physical respiratory disease, and I may add that there is no such thing as a purely psychical respiratory disease, but respiratory diseases are both physical and psychical, and their treatment should be both physical and psychical.

It has been pointed out that disease always exists

*President's Address read before the American Laryngological Association, Washington, D. C., May 9, 1916.

and progresses in a kind of vicious circle, and in this vicious circle are involved psychical as well as physical activities. Just as health has been called a self maintaining circle, so disease may be defined as a self corroding circle, and we may carry the analogy still further by stating that just as departures from health result from a breaking into the self maintaining circle at some point, so disease must be cured by breaking into the self corroding circle at some point, and as some one has said, if the gateway by which the vicious circle of disease may be entered is in the psychic area of the circle, the disease may be regarded as functional, but if it is in the physical area, it is organic.

This, by the way, gives us a new and more practical definition of the terms, organic and functional, in their relation to disease, and it opens the way also for more rational and scientific therapeutical measures. According to this distinction, the treatment of the so called functional diseases of the respiratory tract, or indeed of any other tract, should be largely psychical in character.

It is true that psychotherapy has been practised after a fashion since the very beginning of the history of medicine, but that this form of therapy has not kept pace with other forms must be apparent to all, and there are good reasons why this should be so, the chief being the fact that the successful practice of psychotherapy requires on the part of the practitioner the profoundest knowledge of both medicine and man, and especially of man. The fact is that few of us are mentally and temperamentally capable of practising psychotherapy in the way that it should be practised, and even the improved curricula of the schools are not offering the rising generation of specialists the kind of assistance they should have.

We all practise psychotherapy incidentally and in a half hearted way, but this is not enough. The modern physician should be able to differentiate clearly between diseases which have a purely physical basis and those which are due to psychical conditions. He should know whether the disease is organic or functional according to the definitions which have been given, and when he has decided to which class it belongs, he should know how to explain the situation. If the patient's difficulties chance not to have an organic basis, the physician should be able to persuade him that no operative interference can possibly give him relief.

If, for example, a man's cough is a nervous or habit cough due to fear of some permanent disability or serious pulmonary disease, this fact must be fully revealed to him in the clearest possible language and his reason must be appealed to in an educative way in order to enlist his psychic cooperation in his cure.

To remove a man's tonsils for the cure of an irritation in the pharynx having its basis merely in a psychoneurotic habit, can only bring discredit upon the surgeon and further disaster to the patient, and to operate merely for the psychical effect of the operation is also exceedingly questionable surgery. Many a tonsil has been sacrificed as well as many a turbinate bone for no other reason than that the patient is suffering from some purely psychical disability, and the sooner this fact is fully realized by the laryngologist and the rhinologist, the better it will be for all concerned.

Moreover, when the diagnosis of a functional disability having a psychical basis is established it is not enough to point out to our patients the true nature of their affection, and to tell them what they must do to be saved, nor is it enough to show them how to do the things that are necessary as well for the body as the soul, but we must actually make them do these things or gradually teach them to do them by a systematic course of reasoning and instruction.

The successful practice of psychotherapy requires the whole man, and the whole man at this best. Of all the successful psychotherapists whom I have met, the late Dr. Weir Mitchell was the most successful. Although he rarely used the term psychotherapy, yet he practised it in a most pronounced and effective manner. It should be said, however, that his was not the purest type of psychotherapy, but that his practice combined in a most skillful manner both physicotherapy and psychotherapy.

Psychotherapy reduced to its final essence depends for success upon the subtle influence which one personality is able to bring to bear upon another and weaker personality. This influence can be exerted by the physician to its fullest extent only when he is thoroughly familiar with all of the constituent elements of the particular personality which he desires to change or rehabilitate. There must be no secrets between the patient and his physician. The patient must be made to feel reasonably sure that the physician knows all, and knowing all can do all that is necessary to bring about a cure in his particular case. In other words, the physician must have made what has been called a psychognosis as well as a diagnosis, before he can hope to influence the personality of his patient.

The method of psychanalysis as suggested by Freud and his followers has been practised with varying results. It is based upon the theory that psychical or functional diseases are due to unconscious or rather subconscious conditions of mind which must be brought up out of their hidden depths into the domain of consciousness before a cure can be accomplished.

The methods adopted for this psychical analysis are through certain complicated association tests and a study of dreams. It is a very ingenious theory and one perhaps more ingenious than practical, but in certain complicated cases and in skilled hands its use may prove to be of great value. In but few instances, however, is it necessary or superior to psychotherapy practised by the methods known as persuasion, education, and reeducation.

The successful practitioner of medicine or of any phase or specialty of medicine must be a psychologist and a teacher. He must be able to differentiate between functional and organic diseases; he must know whether the self maintaining circle of health has been broken into by the psychical or physical gateway, in order that he may know just what particular therapy is indicated. He must understand that although organic lesions are found, the disease originally may have been wholly psychical, and in

such instances it is not enough to cure the organic disease, but he must remove its original cause, else a permanent cure will be quite impossible.

All this has a special bearing upon the treatment of diseases of the respiratory tract, for many of them are purely functional, and of psychical origin. It is important, therefore, for us so to understand the psychology of these diseases and the psychology of human nature as to be able to distinguish between those of our patients who are psychopaths and neuropaths and those who are suffering from actual organic diseases which may be relieved and cured by medical and surgical treatment.

It is probably not going too far to say that quite as many of the habitués of our offices and clinics are there because of psychical as of physical disorders, and we must recognize the fact that to treat the purely psychical cases by physical measures is not only useless but in many instances absolutely harmful.

It is well known that to fix the psychism on a particular organ, like the nose or throat, is sufficient in itself to cause to develop the various neuroses of these organs, such as difficult nasal breathing, sensations of intranasal pressure, and even catarrhal states of the nasopharyngeal mucous membrane.

Voice and speech difficulties also arise and are continued as a result of this psychical condition. Laryngeal coughs and the so called sore throats of clergymen and actors are frequently the results of emotional disturbances arising from fear of the disability to which these conditions may give rise.

To fix the attention strongly upon anything always interferes with normal respiratory interchange in that it tends to diminish the frequency and rhythm of the respiratory movements, and to fix the attention upon disturbances of respiration, such as we find in certain forms of asthma and in so called dyspnea, apnea, and polypnea, is doubly injurious because it tends both to aggravate the affection and to establish it as a more or less permanent psychophysical habit.

Whether or not the diseased condition was originally functional and of psychical origin, it must always have in it a psychical element, although it may have become chronic in character and even though it may appear to have an organic basis. For example, faulty respiratory interchange, whatever may be its cause, may result in enlarged or even hypertrophied turbinate bodies, especially when the breathing is in large part oral rather than nasal, on the principle that the disuse of an organ tends to render it organically as well as functionally less efficient in its action; and obviously the removal of such turbinate bodies by operative measures will not result in normal breathing unless at the same time we correct the faulty habits of breathing which were in great measure at least the original cause of the apparent organic lesions. It is not enough, therefore, either in acute or chronic cases, to do operations for the correction of disturbed functions without at the same time or immediately thereafter doing something in an educational way to correct the faulty habits which accompany, either as cause or result, the conditions that we are seeking to modify or cure.

Another good example of the psychophysical habits that arise owing to functional disturbances due to organic lesions is found in the cleft palate speech. The individual with a cleft palate acquires a characteristic speech, and this speech is the result of faulty psychical as well as faulty physical conditions. When the cleft palate speech has once developed, no amount of adequacy and efficiency of the palate brought about by operative measures can in itself appreciably change or improve the speech. This is true because the psychism of the individual has come to accept the cleft palate speech as being normal speech, and this psychical condition must be changed before anything like correct speech can be given to him.

The principle obtains in all our operations upon the respiratory tract, the object of which is to correct faulty function. We have not done our whole duty, therefore, in the removal of tonsils and adenoids until we have by medicoeducational methods taught our patient to overcome the faulty psychophysical habits to which the hypertrophied or diseased glands have given rise, nor have we done our whole duty in a submucous septum operation until we have by medicoeducational measures taught our patient properly to use the free nasal channels for respiratory purposes.

Full recognition has been given to the fact that respiratory difficulties, such as certain forms of asthma, have been due to reflex nervous action following intranasal obstruction and pressure, and some uncomplicated cases have undoubtedly been relieved by the correction of the intranasal deformities, but the percentage of cures resulting from intranasal operations for the relief of asthma and other respiratory affections would be far greater if the operative procedures were accompanied and followed by the correction of the faulty respiratory habits engendered by the original abnormal conditions within the nostrils.

Examples of this kind could easily be multiplied, but enough has been said to show that psychotherapy in the form of education and reeducation should always be used in addition to the necessary medical and surgical measures for the relief of disturbed respiratory, phonatory, and articulatory functions.

The value of this principle is apparent in the particular so called specialty within a specialty to which I have given much of my time and energy, namely, the disorders of speech, and I may say that the treatment of these disorders differs not from that of other disorders of function found in the respiratory tract.

An historical review of stammering reveals the fact that surgery of the phonatory and articulatory organs was formerly looked upon as the great panacea for the cure of this affection. Distinguished surgeons operated not only upon diseased conditions and abnormal structures, but also upon perfectly normal structures, not hesitating, for example, to remove cross sections of the tongue and portions of the epiglottis in the hope of curing stammering. To us of the present day this practice would appear to be absurd, and that any sane practitioner of medicine could even think of such a thing is inconceivable,

and yet it was done by some of the best surgeons of the nineteenth century.

We now know that stammering, in the great majority of instances, is of psychical and not of physical origin, and that to cure stammering psychotherapy is quite as important, and in some instances more important than physicotherapy. We know, in other words, that stammering, at least in its chronic forms, is essentially a psychoneurosis, whatever may have been the original cause, and that stammering speech, like the cleft palate speech, can be cured only by a happy combination of psychotherapeutical measures with the necessary medical and surgical procedures.

What is true of stammering is equally true, not only of other forms of defects of speech, such as pseudolalia or faulty articulation, but of many of the other more or less serious functional disorders of the respiratory tract, and as we of the medical profession have been slow in recognizing that stammering and other defects of speech are largely of psychopathical origin and require for their cure psychotherapeutical measures, so have we been slow in recognizing that many forms of asthma, sore throat, and difficult nasal breathing are of similar origin and require similar treatment.

In no specialty of medicine is the importance of these matters so apparent as in our own, for in no specialty is the psychical element so great a factor in the causation, not only of functional, but of organic disorders as well. It must not be overlooked that faulty methods of breathing, vocalization, and articulation, although at first of psychical origin, frequently result in organic diseases which cannot be differentiated from diseases having purely physical bases.

In our discussion of this subject, however, we should try not to differentiate too closely between the psychical and physical, and we should keep in mind that these phenomena are closely related and equally demonstrable as objective entities. A study of the psychobiological phenomena as they appear in a given individual is merely a study of his reactions to his environment, or, in other words, a study of what has been called his mentation, behavior, and personality.

The new psychology, therefore, teaches us not merely how to treat diseases of special organs, such as the larynx, the nose, or the ear, but also how to treat the patient himself or the reactions of the patient to these particular diseases. Moreover, a knowledge of this psychology will greatly broaden the scope of our work, and it will also tend, as Dr. Adolph Meyer has said, to make a medical education absolutely necessary to those desiring to practise the various forms of the healing art.

The suggestion of the desirability of treating the patient rather than the disease is not a new one, but the principle involved has met with only scant favor, and as long as medical practitioners persist in ignoring it, so long shall we have nonmedical practitioners, such as Christian scientists, osteopaths, hydropaths, and all the others of their kind, actually invading our own fields of operation, and so long also shall we fail to live up to our high calling in the practice of medicine.

1627 Walnut Street.

THE HOSPITAL TREATMENT OF SIMPLE CHOREA.

By Pearce Bailey, M. D.,
New York,
Physician to the Neurological Institute.

Experience with simple chorea has led us to believe that rest in bed and isolation are the essential conditions in its treatment and that they are effective. With few exceptions, this simple method as carried out in hospital wards may be counted on to relieve the symptoms promptly and with a small percentage of relapses. This statement is based largely on the clinical behavior of patients treated in the third division of the Neurological Institute during the past six years. Of patients coming to the dispensary, about one in four are admitted to the hospital. These admissions represent the severer types of the disease, many of the children being unable to articulate in a way to be understood, unable to feed themselves, or to walk. Forty-eight cases have been treated in the third division, ranging regarding sex, age, and stay in hospital as follows:

Sex.		Ages.	
Males	18	Eight to 14 years	30
Females	30	Over 14 years	12
		Under 8 years	6

Stay in hospital.

Up to 10 days	12
From 10 to 20 days	15
From 20 to 30 days	17
Over 30 days	4

Age. Simple chorea seems to be extremely rare after sixteen years of age. Coming on after that time, it indicates either a pronounced rheumatic tendency or else previous attacks of chorea improperly cured. It may also be an indication after this age of abdominal conditions. In one of our cases, in a woman of twenty-four years, chorea was associated with an ectopic kidney. On operation, the chorea immediately ceased. In another case which complicated pregnancy, a miscarriage occurred in the hospital and the chorea immediately ceased.

Characteristics. The patients have been admitted usually from the dispensary, but many have been sent directly by their physicians. The disease in patients who enter the hospital has usually been in existence for several weeks or months, and various kinds of treatment have failed.

Chorea seems to be a disease which school teachers do not recognize until it fairly leaps to their eyes. We have had many cases in which the children were in and out of school with what must have been a pronounced chorea, but which was not taken in hand nor even noticed by the teachers. The severest cases are those in which the rheumatic history is unmistakable, and are usually associated with cardiac conditions, the most common of which are rapid pulse, murmurs of various kinds, and enlargement. A small proportion of the patients are mentally defective. Chorea occurs in two ways in mental defectives. In the first it consists of choreiform twitchings of the muscles. In this type the twitchings do not follow the ordinary clinical type of chorea, but come and go without disturbing the patient particularly. Other defectives have regular attacks of chorea like other children. This latter variety has a bad effect on the children, especially on those badly brought up. Under these conditions the

children become extremely restless, rebellious, have outbursts of temper, and are hard to manage.

Treatment. The treatment consists principally of rest and isolation. This means rest in bed, with curtains drawn, and no communications allowed with other patients in the ward and no visitors. In certain cases, cold packs are given, and in the presence of rheumatic history, and even without it, rheumatic remedies, especially aspirin, are prescribed. In a few violent cases we have used lumbar puncture, which, when the cerebrospinal fluid is under increased pressure, seems to diminish the movements very promptly. In view, however, of the long time the disease has existed before it comes to us and the violence of the motor restlessness, it seems probable that several weeks' complete rest is necessary to overcome the irritability of the nervous system which must have been engendered, so that even if after a lumbar puncture all the symptoms disappear, it seems to us wiser to insist whenever possible on a three or four weeks' treatment for the purpose of reestablishing the tone of the nervous system. We have rarely found it necessary to give salvarsan.

Stay in hospital. Most of the patients who stay less than ten days leave for some reason other than that directly connected with the disease. In a few patients in whom choreic manifestations disappear in two or three days, the parents have taken the children home. We do not feel, however, that ten days is sufficient time for the treatment of even mild chorea. The period between ten and thirty days is the one in which most of the cases fall. At the end of this period in the majority of cases no twitchings have been noticeable for some time, and the patient, so far as we can see, is well, except for cardiac murmurs or lesions which may still persist. A few patients who have stayed longer than thirty days have either had cases of very long standing, or else are those in whom the chorea seemed merely another manifestation of a deeply imbedded long standing rheumatic tendency. Sleep after the first few days is generally very good, although some restlessness and talking may persist for a longer period.

We have been unable to draw inferences from the condition of nutrition. Some patients who do not do particularly well, gain in weight; others in whom the twitchings disappear rapidly, lose weight, but in the majority there is no material change in weight during the stay in the hospital.

Relapses. Relapses occur, but they are comparatively infrequent after hospital treatment. Only three patients have been treated in the hospital on repeated admissions. We are further inclined to believe that relapses are rare, from the fact that only thirteen of the forty-eight patients discharged from the hospital have reported subsequently to the dispensary. Those who have thus reported, with two or three exceptions, have not come more than once or twice and then only for some simple remedy. One patient came back after many months' interval to be treated, not for chorea, but for another manifestation of rheumatic tendency, viz., erythema multiforme. Another came back, after several years of intermittent choreic symptoms, for treatment of a heart lesion; in this patient all twitchings had disappeared.

We consider this result quite encouraging, because so many patients have come to us with histories of previous attacks; several patients have had three or four.

Our general conclusions from cases of chorea treated in the hospital are that by rest and seclusion, when the treatment is extended over a reasonable period, chorea can be permanently cured without much danger of a relapse, and in view of the general relapsing tendency of the disease, we feel that the treatment of chorea is one of the most important functions of a neurological hospital.

52 West Fifty-third Street.

INFECTIVE PULMONARY ENDARTERITIS OCCURRING WITH PATENT DUCTUS ARTERIOSUS.*

With Some Observations on Pregnancy and Heart Disease.

By Morris Manges, M. D.,

New York,

Professor of Clinical Medicine, University and Bellevue Hospital Medical College; Visiting Physician, Mount Sinai Hospital.

Case. Mrs. R. B., thirty-two years old, housewife, entered Mt. Sinai Hospital, October 21, 1915. Previous history was negative, except for severe grippe fifteen years ago. No tonsillitis or rheumatism. She always considered herself well until eleven years ago, when, at the time of her marriage, she applied for life insurance and to her surprise was rejected because of heart disease. She had had no cardiac symptoms then or as a child. She had borne two children, now five and three years old; there were no cardiac symptoms during pregnancy or labor.

Present history: For the past three months she had had fever and chilliness; there were also vague joint pains, cardiac palpitation, and increasing weakness. Examination showed a slight cyanosis. The heart was moderately enlarged to the right and to the left, the right border being just beyond the right sternal border; the left border, four and three quarter inches to the left of the midline. Apex normal. There was a Gerhardt dullness in the first and second left spaces, reaching half an inch from the left sternal border. At the apex there was a soft systolic blowing murmur; in the second left space and transmitted into the vessels of the neck, there was a loud rumbling systolic murmur, which ran into the diastole. The second pulmonary sound was sharply accentuated. The lower border of the liver was one finger's breadth below the costal border; the spleen extended to two inches below the costal border. Around both legs there was a crop of small petechiæ.

The blood examination showed 5,500,000 red blood cells; 9,000 white blood cells, eighty-seven per cent. polynuclear, sixty per cent. hemoglobin. Wassermann and Widal were both negative. Blood culture showed a nonhemolytic streptococcus (Streptococcus viridans). Blood pressure: Systolic 105, diastolic 60. Urine: Trace of albumin, no casts, and no red blood cells.

Fluoroscopy (Doctor Wessler) showed a heart normal in size and position. The pulmonary artery was considerably enlarged and pulsated vigorously. Aorta normal. The diagnosis was enlarged pulmonary artery which was characteristic of patent ductus arteriosus. The electrocardiagram showed no abnormality. There was no evidence of congenital lesion such as extraordinarily tall R waves or predominant hypertrophy of right ventricle (Dr. B. S. Oppenheimer).

During the first two weeks of her stay in the hospital she had an irregular temperature of 99° to 102° F. Then on November 2nd and 3rd it ranged between 103° and 104°; it was somewhat lower for the next four days; then it rose to 105°; from November 10th to her discharge it ranged from 99° to 102°. Later blood counts showed from 7,800 white blood cells with fifty-three polynuclears, to 15,000

*Read before the American Climatological and Clinical Association, at Washington, D. C., May 10, 1916.

with seventy-nine per cent. polynuclears; the average counts were from 8,000 to 9,000. The murmur became louder and more rumbling and gradually occupied all phases of the cardiac cycle. The second and only other crop of petechiæ developed two months after the first group and was not very abundant. Two additional blood cultures were taken, the first negative, but the second again positive.

At no time did she seem to be very ill, except at the short period of high temperature, and when she had a large infarct of the left lung, on December 25th. After a three months' stay she left the hospital somewhat improved.

The present condition of this woman is unknown, as all efforts to find her have been unsuccessful. Her case is of interest, not only because of the rarity of infective pulmonary endarteritis, but also on account of a number of points of practical importance. First, the occurrence of patent ductus arteriosus and infective endarteritis, which is very rare. Hamilton and Abbott (1), who have collected the literature up to 1914, have been able to gather ten cases and have reported a case of their own. Doctor Libman has informed me that he has observed two cases (both without autopsy) which he will publish elsewhere. The present case brings the total number up to fourteen.

Although there is no post mortem evidence to sustain it, the history and physical signs warrant the diagnosis of infective pulmonary endarteritis. There was no evidence of infective endocarditis unless we assume that the soft systolic apical murmur indicates involvement of the mitral valve. The murmur was not constant and its character and the other physical signs do not warrant the diagnosis of endocarditis. No case of infective endocarditis which I have observed has presented such a variable murmur. The large pulmonary infarct would have been a very unusual occurrence in an uncomplicated mitral endocarditis, because such an embolus would have lodged in the greater circulation. We are therefore justified in assuming that the pathological findings in this patient are identical with those which are so well described and illustrated in Hamilton and Abbott's article.

That infective pulmonary endarteritis should occur in congenital cardiac lesions is by no means astonishing, as the conditions which favor bacterial infection are identical with those which exist in the hearts and vessels in acquired endocarditis and endarteritis. That the number of cases of bacterial infection in congenital cardiac diseases should be largest in patent ductus arteriosus is readily explained by the fact that, of all the congenital lesions, patent ductus arteriosus is the one which is most conducive to longevity, as will be referred to later on.

The clinical features agree in nearly all ways with the case reported by Hamilton and Abbott. The special points of diagnosis are well summed up by Hamilton and Abbott, in whose paper the literature of the subject will be found, together with an analysis of the cases reported.

The mild course of the disease in this case was a striking feature; during the long period of observation she did not seem to be very ill and often she was kept in bed with difficulty. It was only when she had the rise of temperature to 104-5° F. and also when she had a pulmonary infarct that she was willing to consider herself sick. Hence, unless we are on the watch for such possibilities, the diagnosis may readily be missed. The only showers of petechiæ which she had were two in number and these were scanty and on the legs only. This will also explain the absence of red blood cells in her urine. In doubtful cases, where the blood culture is negative, the presence of red cells in the urine may be of considerable corroborative value.

I would also direct attention to the course of the fever and the low blood counts. For the greater part of the time the fever was low, below 102° F. A low grade of fever without chills does not exclude the existence of Streptococcus viridans in the blood. Hence the rule which has been followed in Mt. Sinai Hospital to take blood cultures in all cardiac patients who have even low temperatures. A number of cases of infective endocarditis have thus been discovered where the clinical course would not have led us to suspect its existence.

The blood count ranged from 7,800 to 10,400 and only once did it rise to 15,000. The polynuclear count was also low, ranging from about fifty-three per cent. to eighty per cent.

I believe these cases are much more common in adults than is usually suspected, though Abbott (2) asserts that as an isolated lesion, patent ductus arteriosus is among the more infrequent of cardiac anomalies. To too many physicians the diagnosis of congenital cardiac disease is improbable unless there are more or less cyanosis, dyspnea, and clubbed fingers, as well as a history which goes back to early childhood. Nothing is further away from the real condition than such a view. If such symptoms were present to any degree in childhood, adult age would never have been reached; for these children usually succumb to some intercurrent disease. The present case shows how erroneous this view is, and my experience in a number of other cases of congenital cardiac disease which I have observed in adults, corroborates this statement. I will cite only four cases.

The first case was that of a married woman, thirty-five years old, who was admitted for a diffuse adenocarcinosis of the stomach with peritoneal and intestinal metastases and ascites. The physical examination revealed a patent ductus arteriosus, but she had never had cardiac symptoms of any kind, and, although she had to be tapped many times for the marked ascites due to cancer, her symptoms were in no way aggravated by the cardiac lesion.

The second case was a woman, thirty years old, with patent ductus arteriosus and Basedow's disease. Until the onset of the Basedow's disease, five years before her admission to the hospital, she had never had palpitation of the heart or cardiac symptoms.

The third case was a woman, fifty years of age, with patent ductus arteriosus. She entered the hospital for an attack of sciatica. She had never had symptoms until two years ago. These were not marked, however, and the only complaint that she made during her stay in the hospital was of a slight dyspnea and a moderate edema of the feet.

Another of the congenital lesions in adults is coarctation of the aorta, a very marked example of which I would refer to in a man, fifty-eight years of age, who died from a new growth of the lung. He never had symptoms directly referable to the circulatory system, and yet, at the autopsy a very marked coarctation of the aorta was found.

When the congenital lesions exist singly without other complicating congenital defect, very few circu-

latory symptoms are present, the only evidence of them being the physical signs.

The diagnosis of patent ductus arteriosus may readily be made by the following Hochsinger's (3) rules:

1. Palpable and much accentuated second pulmonic sound.
2. Gerhardt's sign.
3. Thrill felt in the jugulum.
4. Enlarged pulmonary artery in the x ray picture.
5. Murmur in second left intercostal space, which in infancy is always systolic in uncomplicated cases, but as dilatation from the pulmonary artery develops may extend into the diastole.

This patient also brings up another point of the greatest practical importance. I refer to the fact that this woman with a marked congenital cardiac lesion bore two children and went through both labors without trouble. This is also true of two of the cases of patent ductus arteriosus which have already been referred to. One, the case of the woman with the adenocarcinoma who bore two children, and the other, which is most striking of all, the woman, fifty years of age, who in spite of a patent ductus arteriosus had borne eight children and had also had three miscarriages, all without manifestations from her heart!

What is true of these women with congenital cardiac disease is also true of acquired cardiac disease, viz., the ease with which children are borne by these patients. I make this statement as the result of having paid particular attention to this question during a long hospital experience. I have always inquired of the women who were admitted to my service with cardiac lesions and who had borne children, whether there had been any unusual trouble during the pregnancy or the labor. Usually the answer came in the negative; indeed, they seemed to be astonished that such a question should be put to them. Further corroboration of this statement is to be found in the fact that most of these women had borne two or more children. I know of one case of a woman with valvular disease who had borne eleven children without discomfort from her heart.

There is only one lesion which gives trouble, namely, mitral stenosis, and this is true only in the uncomplicated type. When there is an associated mitral regurgitation, no great difference is reported in the pregnancy or the labor. That the addition of the mitral regurgitation to the mitral stenosis should ease the cardiac condition is self evident.

I cannot bring statistical data to prove these statements, as I have never tabulated these cases. A fact definitely stated as being based upon twenty-three years' experience in an active medical service is more convincing than any array of figures. This experience is so opposed to the general teaching, that it would be a matter of interest to have this point discussed today.

A striking illustration of the prevailing views as to the dangers attending labors in congenital cardiac lesions is provided by Rosenthal (4), who reported a woman with patent ductus arteriosus upon whom a Cæsarean section was performed, so great were the fears that she would not go through her labor. Up to the time of labor she presented no untoward symptoms; but, as soon as labor set in, the Cæsarean section was performed. This operation she bore as a normal individual would have done, and made an uneventful recovery.

I wish to add that these views in regard to cardiac women refer to hospital patients. In private practice my experience has not been the same. I have not seen so many pregnant cardiac women, as prevailing views in the profession do not encourage such women to marry or to have children. If, perchance, they do become pregnant, abortion is too often advised. The poor patients, whose lives have not been made miserable by the chance of finding a murmur and whose compensated hearts have not been so needlessly and harmfully disturbed and coddled by over solicitous physicians, usually fare better than their rich sisters.

I would not be misunderstood as being too sweeping in my remarks. What I urge is that compensated hearts (uncomplicated mitral stenosis excepted) should be regarded in a much more favorable light as regards marriage and pregnancy than is now the rule.

ACUTE ANTERIOR POLIOMYELITIS.

Some Considerations Regarding Recognition of Its Clinical Types, As Revealed in the Present Experience in the States of Pennsylvania and New Jersey.

BY ALFRED GORDON, M. D.,
Philadelphia.

The present remarks have reference exclusively to the diagnostic elements of infantile paralysis. Not infrequently the diagnosis has been either overlooked or else was incorrect from the beginning. The latter occurred chiefly by reason of associated unusual symptoms. The erroneous diagnosis led to neglect of isolation, hence to contamination of healthy members of the same families and of friends. The object of the present contribution is to lay special emphasis on the common manifestations which are apt to obscure the main underlying pathological condition.

At the time of writing these notes the writer's experience concerns forty-five cases seen chiefly in consultation. Among them eleven cases presented extremely slight symptoms. In all the onset was similar, namely, slight malaise with gastrointestinal disturbances (generally diarrhea). A sudden weakness in one or both lower limbs followed. The patellar tendon reflexes were somewhat diminished, but at no time abolished. The lessening of the knee jerks was equal in both legs in the entire series of eleven cases. As an interesting feature may be mentioned the greater decrease of the tendo Achillis reflex than of the knee jerks in six cases, also the disappearance of the same reflex in two cases, finally total preservation of the Achilles reflex in three cases. This group of cases was instructive from the stand-

point of diagnosis. The abolition of the Achilles reflex together with the typical onset of the disease was sufficient to make a correct diagnosis. The pronounced diminution of the Achilles reflex together with a certain amount of weakness of the lower limbs, also the sudden onset, enabled me to recognize anterior poliomyelitis. The amount of weakness was so slight in some cases that the disease was overlooked by the attending physicians and various other diagnoses were made, such as nervous exhaustion, indigestion, heat exhaustion, and others. The condition of the reflexes is a very important diagnostic element in this affection. A number of times this symptom was intentionally ignored, as no importance whatever was attached to it, while in reality it was the deciding factor in the recognition of poliomyelitis.

The chief elements in very mild and abortive cases are: The onset and the state of reflexes. Among the latter, not only the patellar, but also the Achilles tendon reflex should be investigated. Diminution of both, abolition of one in spite of preservation of the other, are all symptoms of the affection of great diagnostic value.

Among the thirty-three remaining cases there were: Fifteen of the usual type, eight of the meningeal, three of the bulbar, and three of the cerebrospinal varieties. The remaining four presented certain misleading symptoms which will be discussed later. The fifteen typical cases presented nothing unusual. There were flaccidity, paralysis, total loss of reflexes, also the characteristic onset. The lower extremities alone were involved in eight cases; one arm and the homolateral leg in two cases, one arm and heterolateral leg in one case and one arm and both legs in one case. The diagnosis in all fifteen cases was made correctly.

The eight meningeal cases were not diagnosed correctly. The patients suffered pain along the spinal muscles, rigidity of the latter and of the neck, and some pain in the legs. The onset in these cases was without gastrointestinal disorder, but there was a slight elevation of temperature. The impression of the attending physicians was that of frank cases of meningitis, either tuberculous (five cases), or serous (one case) or of the meningococcus type (two cases). The state of the reflexes was totally ignored, hence the errors. In fact, soon and in some instances very rapidly, the rigidity of the neck and spinal muscles subsided considerably; pain, however, remained in the lower extremities. In spite of a diminution of muscular rigidity, of absence of Kernig's sign, and of general amelioration, the diagnosis was maintained to be meningitis. The examination for reflexes revealed a total absence of patellar and Achilles tendon reactions; the paralysis was flaccid. The diagnosis of poliomyelitis could not be doubted. Lumbar punctures failed to reveal by direct and cultural methods the presence of either tuberculosis or meningococcus microorganisms. In two of these cases the erroneous diagnosis led to disastrous results. As no isolation was practised and no preventive measures were taken, other children of these two families fell victims of the disease.

Another source of diagnostic error was found in the bulbar cases (three). One child after a temperature of 99.5° and sudden loss of appetite, began to have difficulty in swallowing and at the same time acquired a left facial palsy of the peripheral type. Also the child had some stiffness of the neck, the diagnosis of meningitis was made, and other children and friends were permitted to be in contact with the patient. The child's condition grew worse, deglutition became more and more embarrassed and liquids regurgitated through the nose. Upon examination I found that in addition to these manifestations there was a distinct paresis of the lower extremities with diminished patellar tendon reflexes and total absence of the tendo Achillis reaction on both sides. Evidently I was in presence of a poliomyelitis of the medulla and spinal cord, but the conspicuous symptoms of the medulla prevented the attending physician from makig a complete examination of the patient at the beginning.

A sister of the patient was permitted to occupy the same bed, with the result that she also acquired the affection, but in her case the lower extremities only were involved. Another patient, a little girl of nine years, presented an almost identical picture with the first, but without the facial palsy. Both patients died within six and eight days respectively. The third bulbar case of poliomyelitis manifested suddenly some difficulty of breathing and swallowing, which gradually became more and more pronounced: the temperature was 100° F. At the time of my examination I found also some weakness in the left arm with decreased biceps and triceps reflexes. This patient died on the fifth day A little cousin was visiting the patient and during the illness was permitted to play with her. A week later she showed a flaccid paralysis of the lower extremities with a diminution of the knee jerks, a typical spinal type of poliomyelitis.

There were three cases of cerebrospinal type of poliomyelitis. Here we had a semicomatose state with rigidity of the neck and a paretic condition of three extremities with marked diminution of all tendon reflexes in the affected limbs. As the stuporous condition lasted three days and was very conspicuous, the diagnosis was made either of cerebral hemorrhage (two cases) or of leptomeningitis (one case). After several lumbar punctures in each case, the cerebral symptoms disappeared, but the spinal symptoms remained. A sister of one of these patients, eleven years old, acquired in ten days infantile paralysis.

The following four cases presented symptoms of an unusual character. Three boys, ten, ten, and eleven years old, and a girl of eleven manifested the typical picture of anterior poliomyelitis, affecting the lower extremities in three cases and one upper and both lower in the fourth case. Upon examination for reflexes the following anomalies were found, which caused the physician in attendance to reject the diagnosis of poliomyelitis, and therefore to expose relatives and friends to infection. In three cases, on stroking the soles of the feet, Babinski's sign was elicited, also in the same cases Oppenheim's and the paradoxical reflexes were distinct. Repeated attempts proved the presence of these reflexes to be correct. Moreover, in one case where Babinski was present in the less affected limb, the paradoxical sign

was present on the same side, but it was heterolateral, viz., on testing for it on the opposite side the extension of the great toe was evident on the side where the Babinski was present. The Oppenheim sign was absent in this case. I had the opportunity to examine the child and treat her for headache one month prior to the onset of poliomyelitis. Jesting with the patient while she was in bed, I happened on several occasions to stroke the soles of her feet and there was always a downward flexion of all the toes. There can be no doubt that the toe phenomenon had here a physiological relation to the poliomyelitis. Reasoning from the standpoint of anatomophysiological information regarding the presence of the toe phenomenon, the physicians in charge concluded that these cases had for proof involvement of the lateral motor tract, hence they were not cases of poliomyelitis. They overlooked, however, the total absence of tendon reflexes. The rejection of the diagnosis of poliomyelitis led them to permit promiscuous crowding of the patient's house, with the result that no preventive measures were taken and within one week one friend acquired the disease. The onset of the disease in these four cases was characteristic; the sudden paralysis of the extremities and its flaccid character, also the total abolition of tendon reflexes, are all manifestations which are too typical of poliomyelitis to require special emphasis. The presence of the toe phenomenon only implies that the lateral motor tract is in a state of irritation through the extension of the pathological process. A simple encroachment on the tract is sufficient to produce the toe phenomenon. The latter occurrence, although unusual in acute poliomyelitis, should not prevent us from recognizing the affection if all other typical symptoms of the latter are present, particularly flaccidity of the musculature and impairment or loss of the tendon reflexes.

Acute anterior poliomyelitis is a disease whose chief underlying condition is an inflammation of the gray matter of the cord, otherwise an inflammation of the central portion of the reflex arc. Paralysis and loss of reflexes are the inevitable consequence of such a condition. According to the degree and intensity of the inflammatory process in the ganglionic cells of the anterior cornua, the degree and intensity of paralysis of the muscles depending on these cells will be manifested. It is consequently urgent in every suspicious case to investigate very carefully the power of the limbs, the locomotion, and the state of reflexes. A mere diminution of these elements is sufficient to give rise to suspicion of poliomyelitis. The latter will especially be correct if the condition is sudden or rapid, if it occurs after an acute onset with malaise, fever, and a gastrointestinal disorder in the midst of apparent good health. We must not be misled by the presence of unusual symptoms, cerebral, meningeal, bulbar, or those referable to other portions of the cord rather than to the cells of the gray matter. As to the bulbar cases, they are identical with the pure spinal cases, with this difference, that while in the latter the cells of the anterior cornua, in the former the cells of the bulbar nuclei are involved. There is a complete analogy among these groups of cells save that they are situated in different places.

Examination of suspicious cases, especially during epidemic periods, must be most thorough. Bearing always in mind the pathology of acute anterior poliomyelitis and the physiology of the ganglionic cells of the anterior cornua of the cord, we must expect at first a motor and reflex disorder in the limbs innervated by corresponding segments of the cord. In the entire clinical picture of the disease these two disturbances are the most essential and therefore the most conspicuous. We have seen above to what disastrous results erroneous diagnoses led. While in some cases the chief symptoms were overlooked, in others they were intentionally ignored. The result was omission of prompt preventive measures for unaffected individuals and extension of infection. The practical importance of prompt recognition of acute poliomyelitis is too evident for me to dilate further on the subject. The unfortunate occurrences mentioned warrant us in laying special emphasis on avoidable diagnostic errors.

ANTERIOR POLIOMYELITIS: THE AFTERMATH.

By Lucy Osborne Wight, M. D.,
New York,
Physician, Day Home and School for Crippled Children; late Assistant Neurologist, Orthopedic Hospital and Dispensary.

When the present alarming epidemic of anterior poliomyelitis is over and the acute cases have so far gone on to recovery that they are dismissed from the hospitals and returned to their homes, a new and difficult problem will present itself; preparation for the prolonged chronic state that will follow. We, who have had the benefit of treating and observing the cases left by the earlier epidemics and the constant sporadic cases, know that the hardest part of this dreadful scourge of childhood comes later. The child, dismissed from the hospital when the acute symptoms have subsided, is returned to its home, where it meets conditions more or less kindly, sanitary, hygienic, and intelligent—usually less—and the long and tedious struggle against crippledom begins.

The department of health has issued and sent the following notice to the parents and guardians of each child discharged as recovered, with lists of the hospitals and dispensaries where orthopedic treatment may be obtained:

> Your child is about to be discharged from the immediate care of the Department of Health, there being no longer any danger of his or her spreading the disease. While in the hospital much has been done to lessen the deformities. There remain, however, weaknesses of ..... With proper care this deformity will be greatly lessened. With neglect it will tend to increase. You are strongly advised to consult your family physician, if he is skilled in the care of deformities, or visit the nearest one of the orthopedic dispensaries in the city given on the enclosed list. In any case, place your child under proper supervision for at least a year, as this tends to lessen permanent disability; neglect may increase deformity.

This is all very good as far as it goes. At first the child is brought with fair regularity two, three, perhaps four times weekly to the clinic. But soon the mother tires of the journey with a heavy helpless child; other duties intervene; household cares

and the other children demand attention. With the slow response to treatment and the lack of visible improvement, the apparent hopelessness of the situation dawns upon her. The visits to the dispensary become irregular, soon cease altogether, and the child is brought to the clinic only when a brace is broken or a deformity becomes so exaggerated and the child so helpless that hope of an operation for relief is entertained. Complete recovery is so rare as to be truly negligible; the prognosis depends on many unknown factors. Early spontaneous recovery of function, however, the recovery of reflexes, and loss of reaction of degeneration are good indications of the reconstruction and regeneration of the nervous system.

A voluntary motion is a complicated process, and even if a large number of centres of the anterior horn have been destroyed by the inflammatory process, under proper stimulation the nerve impulses will sooner or later find a way by which they can pass around the break in the circuit and again innervate the damaged muscles. It is not possible to limit the time for such spontaneous recovery. The experience of the writer is that the greater part, if not all, takes place in from six months to one year. With proper treatment much further recovery can be secured. An early loss of the reaction of degeneration means an early improvement of muscle paresis or weakness, which is much more common than complete loss of power. The persistence of the reaction of degeneration does not necessarily exclude recovery.

The loss of muscle tone, the overstretching of muscles and tendons, and the presence of bone or joint deformity are important factors in prognosis. This overstretching of muscles and tendons is as serious as the actual paralysis, and often ganglion cell recovery is completely masked by the loss of muscle tone. It is therefore of the greatest importance that the limb be placed *at once* in a position of muscle balance or even overcorrection and thus kept in a position less liable to lead to subsequent deformity; to maintain the tone and life of muscle fibre, and to guard against strain, which increases the degeneration of fibres.

A wrist drop, for example, can be kept up by an overstretching of the extensors in a Jones's splint; or a flail shoulder hyperabducted and kept at rest in a suitable splint or position. If paralysis affects trunk and abdominal muscles, so often overlooked, the cloth corset or plaster jacket is imperative. If the legs are affected, the child must not walk or stand, as only the ligaments then maintain the body weight, and they are insufficient if not supported by the muscles. Faulty postures must be guarded against. It is astonishing how much power will return after years of treatment if the muscles have been protected and maintained in their proper position.

Complete rest of the muscles, then, in the physiological position of the joint, is the indicated procedure. There will be difference of opinion as to the length of time of this absolute rest. Experience would lead me to say that each case must be a law unto itself; for the leg cases there is much to lose and nothing to gain by the too early resumption of walking. The moment the child is returned to its home and put on its feet, it resumes the activities of daily life. Restored to general health, it is even more ambitious to exercise than before. Long walks, running, jumping, climbing, etc., are attempted, and all stimulate the unparalyzed muscles. What wonder then if the child soon has a deformity brought on by the contracture of the antagonists? I have seen children in the heaviest braces do the most astonishing "stunts" if left to themselves and unmolested. Needless to say that all this is intensely injurious and retards, impedes, or prevents recovery.

The ideal immediate aftertreatment then, and of vital importance, consists of prolonged rest in bed for a suitable time—each case according to its needs.

After all fever, pain, and tenderness have disappeared, applications of radiant light and heat are in order, not only to the affected muscles, but also along the spine; short, gentle mechanical stimulation by vibration; careful and graded massage; at first only by gentle stroking, then moderate kneading, combined with stroking and bone massage or tapotage.

The massage must go hand in hand with electricity, interrupted galvanism (never more than five ma.), and hot baths of the affected limbs. All of these measures combine to induce a better blood supply, hasten the lymph along its channels, promote warmth, bring nourishment to the part, and thus prevent muscle deterioration. Muscle training and graded exercise are to be begun as soon as warranted by the general condition and may be given to all children over three years of age; even infants may have the muscles gently exercised for a few minutes at a time.

All of the foregoing procedures are to be started very cautiously, no treatment over five minutes, and gradually and methodically increased as strength and function return. Fatigue and overstimulation are extremely detrimental. These treatments should never be given by untrained attendants. Needless to say that diet, correct habits, proper time for sleeping, eating, etc., play their important parts. Under these conditions and with these methods the chances for recovery are immeasurably increased; although it must constantly be borne in mind that restoration of lost muscular power and function is a process which extends over a long, indefinite period of time.

Scores of children in a few weeks will be returned to their homes. Where are they going to receive this ideal treatment? The bringing of these little unfortunates to the crowded dispensary from distant homes, transferred from car to car, sitting around for hours on crowded benches and waiting their turn, then dragged back to the poor unsanitary home and thrust in a corner, while the poor overburdened mother takes up her neglected household duties (usually an entire afternoon is taken up by a visit to the clinic): What wonder then if she is too tired and busy to give the child the warm bath and proper food as she has faithfully promised. All the benefit derived from the treatment is undone, the fatigue and excitement of the journey have counteracted and annihilated all the good that had been attempted. The little victim of circumstance and environment sinks deeper and deeper into his helplessness

and crippledom and into his dreary and unhappy future.

I am afraid we are sadly unprepared for the aftermath of this serious epidemic. It is the intention of the directors of the Day Home and School for Crippled Children, if they can secure sufficient funds for that purpose, to keep open, the year round, their beautiful home on City Island in Pelham Bay Park, now used only for a summer home; take as many children as their means will permit, and work out scientifically and carefully the problems of prevention and cure; later to correct the unavoidable deformity by the best orthopedic skill, so that every child that comes under their care, afflicted with this cruel disease and handicapped at the very threshold of life, may be passed safely over the bridge which connects this crucial period of helplessness and dependence with an independent normal and useful future.

254 West 100th Street.

OCCUPATIONAL SPECIALIZATION IN THE DEFECTIVE.

By Henry M. Friedman, M. D., LL. M.,
New York,
Acting Assistant Surgeon, United States Public Health Service.

So much of the medical work—because of the very infancy of the science—is yet necessarily diagnostic, analytic—really destructive; so much of it is often only a combing of the human pile for the best, for the fittest, and the separation of the remaining into working groups, into studying groups; so little of it is really synthetic, attempting to work up this separated material into something better, making each one fit into his corresponding niche—that the movement for occupational adaptability in early life, for the normal at least, is a step forward. To be complete the movement must include in its deliberations individual variations and defects, both mental and physical, and must try to determine in what special spheres of life these considerations will not act to militate against the individual or against progress. For, with the tendency to specialization in everything, it should not be difficult to find a special sphere for every individual completely outside of the operation of a particular variation or defect.

Even if the question of occupational guidance is too general to be of especial interest to the physician, the question of occupational adaptability for the subnormal and for the defective—for our patients—and their guidance thereto, is peculiarly within the province of the physician as a therapeutist. After doing his utmost for a patient, the physician still has a duty to perform—to advise him what occupations he can enter with respect to the capacities of the nondefective faculties, and which he cannot enter because they necessitate the use of the defective faculties to their greater injury, or, economically, to the inefficiency of the individual.

If a "good result" in medicine or surgery means anything, it means not merely the aimless motion of a member, but the actual practical use to which it can be put. More broadly, the result concerns itself with the occupation to which he can be put in spite of his defect. A good result must be considered in the concrete, perhaps in respect to some particular vocation. Medicine aims not alone at the alleviation of human ills, but at the conversion of the potential in every one, to usefulness, whether normal or defective.

To this end the physician must acquaint himself with the physical, mental, and even temperamental qualities of his patient. He may call to his aid those who know the personal requirements of the various vocations, and then make appropriate comparisons. Indeed, physical conditions in relation to occupation might well receive special treatment, either as a specialty for the physician or in conjunction with lay vocational counsellors.

Thus far the question has concerned itself mainly with the special defective, such as the blind and the mute. Yet there are more of the subnormal, than the definitely abnormal, who deserve first consideration, if only from the force of numbers. Wherever one deals with the defective, whether in the home, in the hospital, or in the clinic, there should be facilities for physical and psychological measurements to seek out the patent faculties, determine their scope, and to what extent they are capable of being trained. Training should then be started early and intensively. No wasteful attempts must be made to train wholly incompetent faculties. Rather they should be abandoned and sacrificed in the interest of the more potent ones. Any peculiar capacity, bent, special inclination, or native ability must be particularly tested out and studied for unusual vocational possibilities. Individual inclination can, however, only be the deciding element when it is found, after training to the highest laboratory capacity, that there is a choice of occupations where the very faculties or senses found to be the best are needed.

In order to obtain a finer division for the defective, this inquiry must not stop after finding a special aptitude for a certain vocation, but must continue until a particular part of it is found where he can do best—in which he can specialize. A defect can often become a blessing in disguise because it brings into relief some special fitness which otherwise would unfortunately not have been brought out. Specialization in the higher vocations and professions is now the rule. There seems to be no reason why specialization, even in the lower ones, cannot be developed, on a higher basis, however, than on the basis of mere machine automatons.

While it may not be quite feasible to run over the whole list of vocations and vocation parts, and to determine for each of them exactly what faculties, and in what degrees, are required and which are not required, it is quite possible to take every defective as he presents himself and to look into his vocational possibilities very thoroughly, at length—even in a very leisurely way, until a suitable occupation from all angles is found for the patient (1). It is upon this determination that the happiness and the welfare of the individual as well as the easing of the burden from society from misfits and incompetents revolves. Whenever we survey the defective of one kind or another who is constantly presenting himself before the physician in his profes-

sional capacity, we cannot help conscientiously asking ourselves what he will do for a living after his discharge as beyond further improvement.

Into whatever endeavor we look, we find that physical efficiency is the important element in success. Acceptance into civil, public, or military positions is usually preceded by a physical examination in an endeavor to select the best and the most fit. Often it is a weeding out process. If none of the applicants attain the set physical standard, none are selected. But when an individual has been rejected for this position, for that position, for every position, because of a gross physical or sensory defect, there yet looms up the question, What is this individual good for in spite of his defect? Is he permanently to be cast aside? It takes no degree of expertness to find defects, to consider every gross defect a drawback to earning one's living in every capacity. Real discrimination in an examiner involves determination not merely as to general unfitness for occupation, but determination as to special fitness for a definite or for a special occupation. Whether a defect affects one's ability to earn a living depends upon the special training the individual has had, perhaps because of the defect, and wherein the latter needs to play no part.

The medical examiner must be familiar with the physical, mental, and psychological requirements of the occupation for which the examination is held. If the applicant's defect is a bar, the examiner can do real constructive work by being able to recommend an occupation where this defect would not be a bar. The examiner must be quick to discern special fitness of other faculties for other occupations. There seems to be a natural tendency to compensate one part of the body for defects in another. Whether this compensation along other paths is real, or only the result of specialization and intensification on nondefective faculties and their consequent greater development, is of no moment (2). It does serve to illustrate that what is credited to Nature can be carried out for the defective by intelligent investigation and effort—and thus a place be found in this life for every one. It is along these lines that the medical examiner's training must run. His must be a specialty. He must not be merely a detective of gross defects. He must take a prominent part among those who do constructive work. He must be able to pass upon psychological defects as well as upon the mental and the physical. Often an individual may have all the physical and mental qualities, yet not the psychological. He is not adapted for that work. His efficiency would have a tendency to be lowered much more than if he had less of the physical and mental but more of the psychological.

On the other hand, it is almost too late for an examiner, unless he finds special aptitudes, to recommend likely occupations to rejected applicants, especially when trained only along unsuitable lines. This recommendation should have been made in early life in the form of appropriate vocational training and guidance. In anticipation of the requirements of vocational life, it becomes the special sphere of the educational systems to have cognizance of the capacities and the limitations of the school child, and to make their training scientific and as much individual as is necessary to take up the slack of its limitations. Where defects are not remediable they must be shunted out of harm's way. In civil life a man may be made to create a place for himself because he has something special to give, perhaps which no one else has to give in like quantity or in such concentration. His defects, no matter how profound, then become immaterial. In every instance special guidance and training would conserve a great deal of good material. The apparently natural genius of some marked mental or physical cripples can be imitated in greater quantities than are now present in the few shining examples. The blanket rejection of defectives must deprive the public of many potential geniuses. Indeed, in certain occupations requiring intensive application, the defective may have an advantage because he is compelled to devote all his attention to the few patent paths. He is not distracted by the activities and the demands of other paths and other senses. The development of this sort of genius must be encouraged by urging all examiners to take notice of the possibilities of the special adaptability of defectives.

Instead of engaging in tiresome and always exhausting mechanical work, children should be encouraged to pursue healthy apprenticeship in previously determined suitable occupations. There would be a larger economical gain in the long run. Material would be created for enlarging many infant industries. Besides, this apprenticeship would fill the place of concrete muscular and psychological exercise, which children would otherwise have little opportunity to get. Ultimately there would be a proper alignment of all work and of all workers. Potentially good workers would not be seeking places now filled by the unsuitable and the incompetent. Too often do we find muscular men doing work requiring little muscle. Much of their energy is going to waste unused. They should engage in occupations where they have an opportunity to use up all their available working energy. There would be less tendency for overplus in one occupation and scarcity in another. There would result a veritable social conservation of energy.

Of course, the question of vocational guidance has no application in unskilled lines of labor. We attempt to lift the people out of this. Yet the lower the scale of the labor, the more serious are physical defects and the less serious the mental—and vice versa. In so much as the mentally and economically defective are forced to choose the lower occupations, just so much does their physical condition affect their ability to earn a living. When they are poor, it is imperative to train them for special vocations. But those who receive preliminary special education purposed to bring them out of the realm of the unskilled, unless they are properly guided in the matter of their education and in the choice of vocation, are fitted for naught else but unskilled labor. They will not do this work because they feel that their education has lifted them out of the social class of the unskilled. These form the unfortunate examples of the lack of proper guidance. They have appetites for better occupations, but no means to satisy them.

Careful survey of the mental, moral, physical, and

hereditary tendencies of the child during school life really begins the preparation for vocational life; there should be a close and accurate understanding of the assets and the liabilities. When the time for actual choice arrived, further investigations would be final and corroborative and not primary. Even with the later acquired defective who becomes the special charge of the physician, the question would be much simplified by consulting the survey records. No survey is complete unless it includes the consideration of individual peculiar gifts, bents, abilities, powers, and shortcomings. Often a careful analysis of the play bent is a useful guide (3). In addition, the psychological laboratory can do practical work with apparatus paralleling the movements, individual and coordinated, of machinery, tools, or individual motions used in various occupations. The individual's ability to keep pace with these movements could be tried out, and he could then be trained in the movements in which he is most proficient. The tests must take special account of the fatigue indexes for the various movements (4); but laboratory determinations are not to be final until after repeated experimentation, perhaps in conjunction with occasional seminar work in the workshops, and after repeated agreement of the psychological findings.

It is obvious that the most extensive psychological tests cannot parallel all the vocational necessities. The supreme test would occur in actual contact with the work—but except for occasional seminar work this is not feasible. Those who accidentally drift into occupations to which they are unsuited, often find out when too late that they have not the qualifications for success because of some mental, physical, or temperamental defect. The laboratory would at least reduce the number of the unadaptable.

Many of these vocational failures, finding themselves barred from success in vocations unwisely entered into, resort to paths of least resistance among the delinquent classes. It is vocational treatment while under restraint that is redeeming so many of them. Vocational ability is an ability to overcome the resistance of the materials worked with—and then of other elements. Those who have not had this training can overcome nothing except that which lies in the path of least resistance—crime. Furthermore, the greater part of this class are mentally and physically defective, and unable, therefore, to assimilate the general training given indiscriminately to the normal as well as the abnormal. They need special individual training and guidance suitable to their defective constitutions. These observations about the criminal can be extended to the vagrant, the pauper, and the ne'er do well classes, who frequent the lodging and the poor houses. They all need to have their patent faculties dug up, trained, developed, exercised, and then harnessed to the proper occupations to work out their own salvation instead of being parasites on the public.

There is so much sensory deficiency which restricts the range of usefulness, of which so much is due to nondevelopment, that the development of the senses must take precedence over nearly every other consideration. While the senses have their maximum capacity, they do not have their maximum acuity until after training. Unless all the senses are trained, some very capable ones will be overlooked, and their effect on the development of the brain will be lost. We can never tell what even a defective organ will do until after we have tried it. We never know its utmost possibilities until we have trained it. A defective but trained faculty is better than an acute but untrained one. Even the training of muscles to better coordination has a marked effect on brain development. It is for this reason that writing is such a factor in mental development. From this source of mental development the illiterate are deprived. To this extent, at least, they are defective. If they are on the border line, literacy will often help to lift them out, while illiteracy will serve to keep them among the defective.

Whatever form of training is used to develop the senses, the effort is justified, even if along lines considered by many as not material—music, painting, etc. Sensory training is the most efficient mental training. Where sensory training in the special arts cannot be carried out, psychological apparatus should be improvised. The psychological exercise would be of benefit. The sensory discipline and the muscular coordination thus obtained would be invaluable in vocational life. Many of the fine arts now have a distinct place in the commercial arts. Those who are physically weak, especially if they have some sensory aptitude, even if not positive genius, could find places for themselves.

For patients having general constitutional diseases or other gross conditions, and yet who must be self supporting, it is quite necessary to advise and to supply proper occupation. This is particularly the case with those predisposed to tuberculosis, for those predisposed to rheumatic conditions, for those with heart lesions, with tendencies to skin disease, with catarrhal conditions and the like, which are so likely to be activated by unsuitable occupations. Those with flat chests and weak musculature must not work at indoor occupations, but must be trained for out of doors. The cardiac subject must not engage in an occupation requiring muscular exertion; the rheumatic in exposed occupations; the catarrhal in dusty or superheated occupations; those with spinal curvature, where heavy lifting is required; those with flat feet in ambulant occupations, etc. Individuals with repulsive facial conditions cannot engage in occupations which require personal contact with the public, even though they are physically and mentally competent. The bar is even greater than if they were afflicted with gross physical deformity or mental defect. They would be the very persons to do the intensive research work so necessary in many callings.

It is important to ascertain whether a man is motor, visual, or auditory minded. There are vocations which require one or other of these types. Work requiring the presence of a type not obtaining in a particular individual must be avoided. Failure is very likely in occupations not chosen with this end in view. It is a waste of time and energy to continue an academic education in a person who is motor minded, no matter what his station in life. It is common experience to find that children who cannot learn in class are extremely good in shop work. It

seems that they are so glad to be relieved of the trying academic studies, that shop work is more than a mere relaxation and pleasure to them, and they apply themselves assiduously to it.

Certain occupations require certain special qualifications regardless of the general composition of the individual. Some occupations require expansive but superficial apperceptions, others require diminutive but deep or detailed ones; some occupations, like telegraphy, stenography, and telephoning, require good auditory memories, others visual—and so on for all occupations. Certain occupations require good muscular coordination, usually obtained in the motor minded. Those with paralyses and muscular asthenic conditions, or with ataxic conditions, are not suited for occupations where quick muscular action is required, either in the carrying out of the work or in quickly avoiding sources of personal danger. Certain occupations require a mathematical turn of mind, like engineering or architecture. Some occupations demand certain temperaments or mental or moral traits, like medicine, law, and theology. Good eyesight is absolutely essential in the transportation occupations.

On the other hand, as we look over the list of occupations, we find that there are certain of them where many defects will not be hindrances, where they may even be of advantage. Because of the power of magnification possessed by myopes they are better fitted for such near work as is required in the engraving or lithographic trades, than the normal or hyperopes, the latter of whom especially, have severe eye strain on doing near work (5). Boiler makers and gunners are probably better after becoming deaf. Blind piano tuners are considered better than others. The highly developed tactile sensibility of the blind makes them desirable in basket weaving and broom making. The remarkable memory of some imbeciles and morons is significant.

As the most important of the senses the visual requirements of vocations deserve first consideration. The range of vision does not vary a great deal if it is considered that in near vision the distance between maximum and minimum is only a matter of inches; and for distant vision often only a matter of feet. For real distance negotiation artificial optical aids are necessary. Real visual acuity has to do with the patency of the retina, the nervous paths, and centres, and not so much with the shape of the eye ball or of the lens. Except where the trouble is retinal or central, defects can usually be corrected to a working basis, at least for some occupations. Almost everywhere individuals are seen getting along with fractional parts of vision. As a general rule, however, it may be said that the lower the plane of the occupation, the less the vision needed to earn a livelihood. But in the transportation occupations, the safety of the public demands the highest degree of visual efficiency, and unless present no amount of inclination or native ability should influence a decision not to engage in them. It is the nature of the occupation, primarily, that must determine the barring effect of visual deficiencies.

It is not often that the loss of one eye, where the other is normal affects one adversely in a vocation. Binocular vision gives greater expanse of vision, monocular gives a smaller field, but greater detail. It is common practice to obscure the vision of one eye where greater concentration of vision is wanted in a small field.

In order to obtain the most from the sense of vision, it is necessary to train it to better observation, and to learn to call to its aid all the sources of orientation. Vision should be educated to perceive more objects in its field, more detail, and more of the circumstances modifying them. How many people "have eyes and see not, ears and hear not!"—because they are not trained in sensory discipline or observation. The power of observation depends upon the discipline and harmony of all the senses. Sensory discipline is as necessary to bodily efficiency as general discipline to universal efficiency (6). Wherever there is not discipline, there is disorganization and dissolution whether in an individual's body, in an organization, or in the whole body of the people.

The possibility of teaching new occupations to those with serious acquired defects, who have as a result been shut out from their occupations, and who must choose new occupations from within restricted ranges, has been demonstrated in Europe as a result of the conflict. The final results must soon begin to appear and be guides for similar work elsewhere, as after injuries in civil life. To what extent new work can be taken up, and to what extent it will affect the ability to earn a livelihood, depends in the adult upon his age, and consequently his retentive ability and mental fixity, as well as on his social standing. The latter often restricts the range of occupations a person is willing to enter. The question must be studied individually. In two people with the same condition, the occupational possibilities may be far from alike. There must be no peremptory disposal of any one as useless material. Even insurance companies do not reject the abnormal absolutely. They make the proper allowances in compiling their risk, but they usually find some insurance for every one. This very principle of finding insurance for every one should be carried out in respect to vocation among the defective—namely, finding occupation for every one.

It is not to be expected, however, that all defectives can be placed in special occupations where they will not be prejudiced in efficiency by their condition. Their very best faculty or sense may be the one destroyed or defective. They must expect to accept a discount, very often in proportion to the degree of their deficiency. Proper vocational methods, however, render self supporting and often positive assets to the community, persons who would otherwise be total losses economically both to themselves and to the community. When there are added to these occupational aids the newer methods of *psychological strategy*, that is, the method of ascertaining under what conditions, during what part of the day, and with what variety of tools, and the like, fatigue is greatest, and under what circumstances the best work is done, then the defective conditions may be almost entirely neutralized (7).

The training of all persons, but particularly of defectives, for suitable occupations, has a great di-

rect influence in reducing the incidence of occupational diseases and accidents. It has been shown in England that the defective is subject to a higher degree of morbidity than the nondefective. Medical examination of applicants before employment reduces this incidence (8). Indeed, the medical examination of prospective workers is the basis for all further determinations regarding them. Attempts must be made to correct defects thus brought to light so as to obviate at least this added risk because of primary infirmity. Besides, the correction of defects will allow many to take up occupations that they are peculiarly fitted for. Occupational inadaptability is the source of much of the vocational morbidity. Hereditary predisposition to disease may in a manner be controlled by avoiding improper occupations, in respect to health heredity and even race. Those with hereditary predisposition to drug or drink had better avoid these industries.

Thus far this question embraces only civil lines of endeavor. In countries where there is universal service in the military organizations, the defective is still uniformly rejected. While he may find a place in civil life, he can find no place in the military. Yet from the standpoint of purely improving a large part of a people needing improvement, military training offers a most useful ground. It can be the best method of converting a defective into an effective citizen. On the other hand, much good material is lost to the military efficiency by maintaining fixed physical standards below which no one is admitted. But while the physical standards are high, the mental are almost entirely neglected, although it is easy to see that there are parts of a military organization where mental development of a high order would be more desirable than physical. Those having the physical requirements are most likely to withstand the hardships incident to military life, have the most staying power, and in general are the best material obtainable. Truly, it can be said of military training that wherever carried out it produces a better type, longer lived—surviving as the fittest—better able to withstand hardship, and able to engage in a more varied range of occupations. The addition of suitable vocational training would take up much of the overproduced energy and better fit the individual for civil life. In an investigation of an industry employing almost exclusively labor from foreign countries where there is compulsory military training, it was found that those having had such training maintained good physical conditions in an atmosphere where almost every one else was more or less defective (9).

At present military training draws too close the selection of the beneficiaries of this training; they form a physical aristocracy as opposed to a plebeian class who are of no value in a military sense. A physical democracy could be produced only by finding a place in the military organization for every one. There are as many varied needs in military life as there are in the civil. There should be few defectives for whom some special place in the unit cannot be found. To be of universal benefit, whether in the betterment of the race, or for immediate or ultimate military purposes, military training must account for every one, but especially for those who are weak and defective and along lines that will give them a usefulness in the unit. They can be trained to fill places that would otherwise have to be filled wastefully by more able bodied individuals. In essence this would be a training of an army of the rejected into an army of specialists. Besides, in drawing for military training or for military use there would always be in reserve a representative average. Later on, lines would be less likely to have a greater percentage of rejects, but would again be representative averages. All the material would be utilized and the defectives knowingly provided for. Placing defectives where they did the best work would serve for a collective efficiency against an individual efficiency (10).

In the end military training is but a form of physical training, and the introduction of selective physical training into the school curriculum would be a preparation for the applied or military training. The step from the universally trained physically to the universally trained militarily, is not a very long one. School and military training usually selects the best for the extreme in training and overlooks those who would benefit most by it (11). Yet in any combat where training of a high degree is necessary, the first line or flower, say, of a military unit succumbs to the first shock. Second or later lines combine poorer physical condition with less, more hurried, and poorer training. Defectives are not compensated assets because they are not chosen and trained for special places. In long continued combats it is with the rejected that they are finally fought out.

Military training would help many otherwise helpless people to find themselves, first physically and then industrially. So many instances of physical weakness are due to faulty posture, sedentary habits, and lack of exercise that to them military training would be a boon—if the examiner realized the cause of their deficiency, and that military training is just what is needed to redeem them (12). The really highly concentrated military body would not then be diluted by the great mass of the untrained. Besides, the discipline enforced in training must be of benefit to the individual and to the community, when properly harnessed, and, if not carried too far, has no effect on individual thought or will.

In the selection of material, height, and even weight, is no longer so important a factor. A tall but slender person is not nearly so desirable as a short but muscular one. The European war has created the place for the bantam. Likewise there is no reason why, say, a hunchback cannot be a sharp shooter, a deaf man a gunner, a flat footed one a driver, etc. In the operation of large ordnance pieces, requiring a great deal of mechanical ability, the range is found by individuals not connected directly with the operation. Likewise, one who has had training in the field is of more value than one with more acute vision but with less ability for interpretation of the visual perceptions. The apparent greater vision of the aborigines was due to their ability to interpret rather than to see better (6).

In conclusion, it is urged that in realizing the vast number of defectives in every community, something more must be done for them than mere diag-

nosis and separation, or mild remedial measures, or custodial care and the like. These solve the problem for neither the defective nor the community. Defects must be ascertained, measured, vocational possibilities inquired into, senses and faculties trained especially in reference to life vocations. Finally, the tendency to relegate the physically defective to the shades of "innocuous desuetude" can best be overcome by selected physical training, democratic military training, in order to develop the physical condition of the people generally, and of the defective population specially.

CONGENITAL SYPHILIS.*

Pathogenesis and Symptoms,

By Walter James Heimann, M. D.,
New York.

With the unaccountable tendency so frequently observed in operations of the human mind to complicate simple things, the subject of congenital syphilis has been made unnecessarily involved. Thus, it is only within recent years that our knowledge of this phase of syphilis has undergone a certain degree of simplification. It is necessary only to point to the historic laws of Colle and Profeta; the disputes as to the source of infection, whether maternal, paternal, or both; to the old name, hereditary syphilis, itself, in order to illustrate the ancient confusion.

On the other hand, to illustrate how this confusion is gradually becoming clarified, the following facts will suffice. The laws of Colle and Profeta have fallen. Abundant evidence exists proving that the apparent immunity of the mother without clinical syphilis to a syphilitic child, or that of a child without clinical syphilis to a syphilitic mother, is not immunity, but actually latent syphilis. The mothers and infants without clinical evidence of the disease nearly all give positive Wassermann reactions, paralleling conditions in the latent stages of the acquired form. The source of congenital syphilis is invariably maternal, and the infection takes place through the placenta. This fact eliminates entirely discussion of congenital lues of paternal origin. The mother may have been infected by the father, or otherwise, but so far as the offspring is concerned, the source of the mother's infection is incidental. The term, hereditary syphilis, is unscientific and has been abandoned. It is not within the province of this paper to define the word, hereditary, but a fundamental distinction exists between this expression and congenital, as the works of Darwin, Romanes, Hertwig, Haeckel, or any other good biologist or embryologist will show. If syphilis were actually an inherited disease, the theory of embryonic transmission of acquired characteristics would need no further support. Syphilis passed on from mother to offspring *in utero*, however, has nothing to do with chromosomes. It is bequeathed far more simply and directly by the actual involvement, through contact, of the placenta, and the invasion of the latter by the mother's spirochetes. Thereupon the placenta, a small participant in the mother's systemic infection, becomes the starting point of the disease in the fetus.

No difference exists between syphilis acquired before birth and that acquired after birth. The disease is always the same, subject to variations in the virulence of the strains of spirochetes and the resistance of the host. Syphilis is syphilis. Any distinctive features the congenital form may possess, not found in the acquired form, are due to biological differences between the unborn and born human being.

Roughly speaking, the infected placenta is the primary lesion in fetal syphilis. Thence the spirochetes are conveyed by means of the placental circulation direct into the fetal blood stream. This serves to disseminate the microorganisms rapidly and effectively, sparing no organ or tissue. The liver is the first fetal organ to receive the placental blood, because the branches of the umbilical vein go direct to this organ, and because of the intimate association of placental and portal circulations. Thus the liver can never escape infection. In postnatal syphilis the entrance of the pathogenic agents into the blood stream is accomplished differently. From the primary lesion the spread of the spirochetes takes place first through the lymphatics. The entrance into the cardiovascular circulatory system is probably effected by transit of the spirochetes from the perivascular lymphatics through the vessel walls into the blood stream. At the moment that this is consummated, such slight differences as there are between prenatal and postnatal syphilis, cease to exist.

The month in which infection of the fetus takes place varies; if very early the fetus will die, become macerated, and be discharged before or at term; if somewhat later, the fetus may survive and be born prematurely, or at the normal time, with the usual evidences of the disease, or as a defective, or as a monstrosity. If the infection occurs very late, for instance in the last month of intrauterine life, the infant is born at term, alive or dead, and with or without objective evidence of syphilis. Much depends upon the type and stage of the mother's syphilis. Should she be the victim of a virulent strain of spirochetes, and in the secondary period, or the secondary latent period, the degree and severity of the fetal disease will probably be greater. Should the mother have become infected in the fifth month of pregnancy, the fetus could not have become involved in less than from two to three months, or in its seventh or eighth month. The later during parturi-

*Read before the Bronx County Medical Society, March 15, 1916.

tion that the maternal infection occurs, the greater the chance of the fetus to escape the disease entirely, or to be born with earlier or milder congenital syphilis, as the case may be.

It is not uncommon to obtain the following account from a woman married about ten years. The first child is nine years old and well. Shortly after the birth of this child there came three miscarriages in the fifth, sixth, and seventh months, respectively, followed by a full term baby with snuffles and an eruption. This baby lived ten days. A year later, a normal infant was born which seemed well and is now five years old. Since its arrival there have been two stillbirths, each child having appeared normal, however, and now there is another baby about nine months old. It appears well, but catches cold easily, and has had a rash about the anus and lips. The mother herself asserts that she has always been healthy, but remembers that after the birth of the first child she had a sore on the vulva and a discharge, but paid no attention to them and consulted no physician. The significance of such a history is deep. The first child just escaped syphilis. Fortunately, he was not nursed. From her second to her fifth pregnancies, the mother was in the secondary and secondary latent stages. During her sixth pregnancy the disease was in abeyance. An exacerbation occurred contemporaneously with the seventh and eighth pregnancies, resulting in stillbirths, and during her ninth pregnancy she was again in a latent period. The Wassermann reaction in this family would be positive in the mother, negative in the first living child, either positive or negative in the second living child, and positive in the third.

Thus, to recapitulate, an interplay of two factors determines the form that congenital syphilis assumes; first, the month of fetal life in which infection occurs, and, secondly, the stage of maternal syphilis during which the transmission is made. In addition to this, a third influencing factor must now be included; namely, therapy. Satisfactory treatment of the mother may prevent fetal infection. Inadequate treatment may have no effect on the offspring, or may diminish the maternal infection and increase the possibilities of the fetus to escape the disease, by prolonging or intensifying the periods of the mother's latency. The older the mother's infection, the less the likelihood of transmission to the child. Thus, in the tertiary period fewer syphilitics are born than in the secondary.

Subject, too, to these factors, the symptoms and pathology of congenital syphilis will vary. Its morbid anatomy corresponds to that of the acquired form. In brief, no tissue or organ is sacred to the spirochete, and thus the symptoms of congenital syphilis include a wide range of possibilities and form numerous pictures, many of which are well known, others rare or uncommon. In this paper only such features of the disease will be dealt with as are found in congenital syphilitics born alive. The symptoms are in the main referable to the skin, eye, ear, liver, spleen, bones, and joints, but other organs are frequently involved, and commonly enough central nervous and mental disturbances, and diseases of the kidney, suprarenal and other ductless glands are observed, and the Wassermann test (1) is positive in ninety-eight per cent. of the cases.

For the sake of simplicity and convenience congenital syphilitics will be divided into the following groups:

1. Patients born with cutaneous and marked systemic evidences.
2. Patients born with cutaneous and slight systemic evidences.
3. Patients born with cutaneous lesions alone, subsequently manifesting systemic evidences.
4. Patients born apparently healthy, acquiring evidences of syphilis within a year.
5. Patients born apparently healthy, acquiring evidences of syphilis between the second and seventh years.
6. Patients born apparently healthy, acquiring evidences of syphilis after the age of seven years. This includes Fournier's group of delayed congenital syphilis.

1. *Patients born with cutaneous and marked systemic evidences.* This form denotes an infection of the fetus in about its fifth month of development. When infected so early, the fetus rarely reaches term alive, but if it should it presents a picture of general maldevelopment; the face is drawn and gives an impression of senility. A papular or bullous dermatosis, the latter the so called pemphigus neonatorum, covers the palms and soles. Mucous patches are present on the lips, in the pharynx, and on the perineum. The liver, spleen, and lymph nodes are found enlarged. The child nurses and cries feebly, and lies quietly as if palsied. This is the so called pseudoparalysis of syphilis due to specific epiphysitis and osteoperiostitis. The bones and joints hurt when the child moves, and are sensitive upon manipulation, the latter eliciting a sharp cry. Usually death occurs shortly after birth, the cause, as a rule, being general weakness, but sometimes pneumonia. This form of pulmonary disease is an interstitial inflammation caused by the activity of the spirochete, and known as white pneumonia. The Wassermann reaction is positive, and spirochetes are demonstrable in the lesions on the mucous membrane and in the eroded papules near the body orifices.

2. *Patients born with cutaneous and slight systemic evidences.* A macular or maculopapular eruption, with pemphigus neonatorum, slight or no snuffles, a certain degree of unwillingness to suckle, some swelling and tenderness of the bones, and even pseudoparalysis characterize this form. If the liver and spleen are not palpable at birth, they soon become so. The Wassermann reaction is positive. Unless treatment is begun promptly, severer symptoms set in, such as iritis and iridochoroiditis, and if therapy is still neglected all the general features of the disease appear, including permanent blindness or deafness, bony deformity, or even death from marasmus.

3. *Patients born with cutaneous lesions alone, subsequently manifesting systemic evidences.* In this form syphilis has been acquired in the seventh or eighth month of fetal development. Thus the symptoms at birth represent those of the early secondary stage. Only suspicious skin lesions may be present, or a frank maculopapular rash, mucous patches, flat condylomata at the anus, or mucous patches in the mouth or on the genitalia. When so fully developed these symptoms indicate the florescent secondary stage. At times, however, only mucous

patches are seen, or groups of papules, or circinate papuloulcerous lesions on the perineum or elsewhere, or tuberoserpiginous gummatous lesions. These symptoms are associated with snuffles. The Wassermann reaction is positive, and spirochetes may be found in the secretion from the mucous lesions. This form indicates fairly good resistance on the part of the baby, and that the disease is in its late secondary, or perhaps even early tertiary stage Should it progress because of neglect of treatment, all the manifestations already mentioned in the first two groups may arise.

4. *Patients born apparently healthy, acquiring evidences of syphilis within a year.* At birth these infants are sound, nurse well, cry lustily, and thrive. Sooner or later, in seventy per cent. of the cases between the third and eighth week, and in ten per cent. of the cases between the third and twelfth month, mild symptoms followed by severer arise. At first the infant's desire to nurse lessens, it ceases to gain, begins to lose in weight, cries, gets hoarse, and has snuffles. Next an eruption appears similar to that noted in the previous group. Adenopathies develop, the digestion begins to suffer, and loss in weight goes on more rapidly. The crying increases and hoarseness grows more pronounced. Bony swelling and tenderness, keratitis, and neuritis of the auditory branch of the eighth nerve may develop. The liver and spleen enlarge. Subject to the age of the infant and the intensity of the digestive disturbance, these symptoms abate or lead to death, unless treatment is timely. The Wassermann reaction is present. According to Knoepfelmacher and Lehndorf, however, this is not the case before the appearance of the rash. This form of the disease is practically always tertiary, or at least very late secondary.

From this point on, congenital syphilis is invariably tertiary in type. The systemic evidences are not generalized, but tend to be selective, picking out organs in widely separated regions. The disease now acts precisely as does late syphilis in the acquired form. It develops a peculiar affinity for the bones, skin, cerebrospinal axis, liver, spleen, and glands.

5. *Patients born apparently healthy, acquiring evidences of syphilis between the second and seventh years.* For the first year of its life the child develops normally or constantly remains somewhat behind the average in physical and even mental progress, but is not actually ill. In the second year, it becomes indolent, makes a rhachitic impression, but lacks the rosary, or it may have actual rickets in conjunction with syphilis. The fontanelles close slowly, or the cranial bones are thinned to a papery consistence in some areas, or thickened into bosses through periosteal infiltration in others. The first of these conditions is called craniotabes; the second, Parrot's nodes. Instead of developing as in normal children, the bridge of the nose remains flat, the tip growing. Thus, this organ acquires the shape of a saddle, through failure to develop, or through the destruction of the small bones composing its structure, chiefly the nasal spine of the frontal bone, the vertical plate of the ethmoid, and the crest of the nasal bones. As a sign of congenital syphilis the saddle nose possesses no value before well on in the second year, as all infants are more or less wanting in the nasal bridge, a fact that Knoepfelmacher used to emphasize to his students. But from the second year on, the sign is of great corroborative value. Other changes in the bones and joints are also significant. The long bones are peculiarly vulnerable, both periosteum and epiphyses being affected. Involvement of the former leads to thickening and deformity of the shaft, of the latter to thickening and deformity of the ends, causing the outlines of the joints to appear abnormal. The tibia is often bent forward so that its convexity is increased and the anterior margin is sharp but roughened. This gives it the general appearance of a sâbre, and on palpation the irregularities of the anterior margin and surfaces may be detected. Röntgenographs reveal all these changes. In the early stages of involvement these alterations cause pain, again giving the symptoms of pseudoparalysis, named after Parrot. Tension of the muscles on the weakened scapula causes abnormalities in its shape, exaggerating its convexity and producing the well known scaphoid scapula. Gummas of the sternoclavicular junction, sternum, and osteoperiosteal cutaneous gummas elsewhere are frequently seen.

The skin and mucous membranes are the site of mucous patches, gummas, circinate, tuberocircinate, or tuberoulcerous lesions and fissures at the mucocutaneous junctions, beside other changes already described.

In the central nervous system and organs of special sense the commonest symptoms are produced by meningitis, pachymeningitis, and hydrocephaly, but tabes, spastic paraplegia (Little's disease) and hemiplegia, and juvenile general paralysis are known. Some cases of epilepsy, mental deficiency, imbecility, and early insanity are due to congenital syphilis. By far the most frequent changes in the organs of special sense are found in the eye and ear. Keratitis, both interstitial and parenchymatous, iridochoroiditis, and auditory nerve neuritis are the commonest; but optic nerve neuritis, retinal pigmentation, and deafness due to gumma in the auditory centre, are met.

The liver practically invariably, and the spleen somewhat less frequently, are enlarged, usually because of chronic interstitial inflammation. At times, however, gummas may develop in the liver, and rarely parenchymatous hepatitis. The last mentioned condition, however, rare as it is, is almost unknown after the first weeks of the congenital syphilitic's existence, when it causes jaundice and other symptoms referable to the liver. The lymphatic glands act as they do in late acquired syphilis. Isolated enlargements are found, with a relative but not constant predilection for the epitrochlears.

6. *Patients born apparently healthy, acquiring evidences of syphilis after the age of seven years.* It is from this point on, or after the time of the second dentition, that Hutchinson's triad, two elements of which have already been considered, comes into prominence. The triad consists of keratitis, or scars resulting therefrom, deafness, or other definite but less hopeless evidence of eighth nerve disease, and the presence of Hutchinsonian teeth. The first two of these have been sufficiently discussed. By the term, Hutchinsonian teeth, is understood an altera-

tion in the shape and position of the two upper incisors of the second set. They converge, their distal margin is shorter than their base, and their edges are notched from corner to corner by a semilunar concavity. The corners themselves are somewhat blunt, and the anterior surfaces of the teeth are often ridged vertically. Although highly suggestive of congenital syphilis, this sign is by no means pathognomonic. Other conditions, notably rickets, may produce similar alterations, while syphilis itself may produce other varieties of dental dystrophy. In addition to the triad, in the retarded variety of congenital lues, all the other conditions enumerated in the previous group may be present, and this period is coincident with life. The very first symptoms of the disease have been known to occur as late as the end of the second, or early in the third decade, and all changes which are characteristic of tertiary acquired syphilis may be found in syphilis congenita tarda. The Wassermann reaction varies according to the laws governing this phenomenon in acquired lues, but all in all it is far more likely to be positive than negative.

Having described, as far as possible, congenital syphilis according to its picture at given ages of the patients, and in given periods of the disease, it will perhaps be not amiss to refer categorically to its common individual manifestations, and to some of the rarer ones. The skin lesions are in the main identical with those seen in the acquired form. Two points, however, merit emphasis: First, bullous syphiloderms are not uncommon, and are usually seen at or soon after birth, chiefly on the palms and soles, in the form of the so called pemphigus of the newborn. Secondly, eroded papules are frequently found on the nates, which are of peculiar significance, since a nonspecific dermatosis closely simulates them. The latter is the erythema gluteale of Leiner, first described by Parrot, in 1877. It is characterized by the presence of erythematous macules, vesicles, or papules, and somewhat resembles pemphigus neonatorum. The lesions rapidly become eroded. Jacquet, Hallopean, and Sevestre pointed out their nonluetic nature, Jacquet calling the vesicular variety *erythème vesiculeux érosif,* and the eroded form *syphiloïde post-érosif.* No spirochetes are found in the lesions and the Wassermann reaction is absent. Leopold has recently reviewed this disease, calling it the napkin eruption, and he was able to prove conclusively that it was caused by alkalies remaining in the napkins after washing with cheap soap and inadequate rinsing. Gummas, wrinkling of the skin, onychia, paronychia, and alopecia are often present. In all these congenital syphiloderms the Wassermann reaction is present.

The lymphatic glands present changes in no wise different from those common to acquired syphilis. Abnormalities in the testes, thymus, thyroid, and pancreas are rare, but in the suprarenal glands somewhat more frequent, causing symptoms referable to these particular organs. The spleen is enlarged in about sixty-two per cent. of all cases at all ages, and the liver is increased in size almost without exception. Often, too, there is jaundice, and at least one form of icterus of the newborn is syphilitic. Usually the cause of this is interstitial hepatitis, but in five per cent. of the cases gummata are found at autopsy.

Although the changes in the bones and joints have already been discussed, the following statistics may be of interest: Still (2) found epiphysitis in twenty per cent. of the cases during the first three months of life; dactylitis in two per cent.; tibial periostitis and craniotabes in forty-seven per cent.; and synovitis and arthritis in seven per cent. Marfan includes congenital syphilis in the causes of rickets. Gaucher and Lévy Bing (3), in an analysis of 347 children with Pott's disease, cold abscess, and coccyditis, found that of fifty-eight in whom there was reason to suspect congenital syphilis, actual evidences of the disease were present in sixty-five per cent.

Among unusual central nervous manifestations precocious tabes must be mentioned, encephalitis, gummas of the brain and cord, juvenile general paralysis of the insane, and Little's disease, while Mott (4) mentions two cases of endarteritis of the circle of Willis, associated with pachymeningitis. He also states that seven per cent. of all cases of epilepsy may be ascribed to congenital syphilis, and that hydrocephalus is also frequently due to this cause. The cerebrospinal fluid in these cases obviously has some characteristics found in central nervous disease caused by acquired syphilis. All types of mental disturbances are possible, the commonest being backwardness. The eye, as already mentioned, shows changes in the cornea, iris, and retina. The iritis is often bilateral, and somewhat more frequent in girls than in boys. Atrophy of the optic nerve and cataract are rare. The most common affection is interstitial keratitis. With the exception of auditory neuritis and otitis media, there are very few diseases of the ear.

Cardiovascular and blood diseases are on the whole uncommon. Among these are arteriosclerosis, aortitis, myocarditis, and endocarditis. Secondary anemia is not infrequent and one form of hemorrhagic disease, syphilis hæmorrhagica neonatorum, characterized by icterus and bleeding from the mucous surfaces and umbilicus, is occasionally encountered. This appears to be due to parenchymatous hepatitis and is always fatal. The respiratory phases of the disease are Virchow's white pneumonia, necrosis of the nasal septum and hard palate, frequently with perforation, laryngitis in fourteen per cent., and snuffles in seventy per cent. of the cases.

The Wassermann reaction is almost invariably positive. According to Noguchi's work already cited, it is present in ninety-six per cent. of all cases, and this author's compilation of the work of other investigators raises the figures to ninety-eight per cent. In a very careful study published by Mark Reuben (5) ninety-nine per cent. were found positive in the early stages of the disease, and fifty per cent. in the later, about paralleling the figures respectively in secondary and tertiary acquired syphilis. During active congenital syphilis the reaction is never absent. It is only during periods of latency and at the onset or waning of activity, that negative results are found.

So concentrated an outline as this perforce had to

be, could barely accomplish more than to sketch in the essential features of congenital syphilis. It is hoped, however, that several points have been sufficiently emphasized to sever from this disease its unnecessary traditional complexities. Congenital syphilis is syphilis acquired during intrauterine life through the placenta, which, after having become infected, plays the part of the primary lesion. From this point the umbilical vein conveys the spirochetes to the fetus, the liver being the first organ involved. Thence the spirochetes are rapidly disseminated throughout the fetus. Here all differences between congenital and acquired syphilis cease to exist. Subject to the month of fetal infection, the infant presents cutaneous and systemic evidences of the disease in its secondary latent or tertiary stages, and the tertiary stage may be protracted for years, or tertiary changes late in adolescent or early in adult life may be the first signs of the congenital infection. Remarkable as such facts may appear, they need cause no astonishment, for in acquired syphilis we see frequently enough examples of freedom from secondary manifestations, the first reappearance of activity occurring twenty years or more after the primary lesion, in the form of tertiary changes. These facts serve only to prove the identity of congenital and acquired syphilis.

In conclusion, one more circumstance must be recorded, and this depends not upon the disease, but upon the age at which the disease is acquired. Congenital syphilis is transmitted to its victim during the most important period of development, namely, before birth, and the struggle to overcome this burden takes place partly before and partly soon after birth. Thus, aside from its actual pathological alterations, the disease may cause all sorts of anomalies of development, physical deformities and dystrophies and mental backwardness, if not actual imbecility, or even insanity. Aside from these considerations, prenatal syphilis and postnatal syphilis are identical.

THE PROBLEMS OF ADOLESCENCE IN RELATION TO SOCIAL HYGIENE.*

By Harold W. Wright, M. D.,
San Francisco.

This paper offers no newly made solution for the problems of sex and adolescence, but only some old truths reemphasized. The problem of sex varies in intensity with different adolescents; for some it is never a conscious problem, but for most of them it is a serious difficulty.

The pathological aspect of the adolescent period, in its relation to sex hygiene, is not dwelt upon in the following pages because of the conviction that if the factors which make for mental health are realized, there will be but little need of concern with disease *per se*.

As to the necessity of any instruction whatever upon this subject there can no longer be any question. Parents, teachers, physicians, and the victims of ignorance have seen and felt too much of the misery which results from a faulty attitude of mind toward not only sex but all the problems of adolescence to be resigned any longer to a *laissez faire* policy. Such a policy might have sufficed for an age almost prehistoric, but it will not avail amid the complex conditions of modern life. Indeed, even among "uncivilized" tribes of people and among the ancient Hebrews, instruction in sex hygiene was a vital part of their religion and their daily lives; and it is somewhat disconcerting to learn that in spite of polygamy the customs of savages in respect to the conduct of their young people before and after marriage show that they possessed ideals of self control and reverence for the functions of sex that put to shame the average man or woman to today.

To the well born child all the virtues are natural and not painfully acquired; speak to his heart and the man becomes suddenly virtuous.—Emerson.

Heaven lies about us in our infancy,
Shades of the prison house too soon begin to close
Upon the growing boy.

—Wordsworth.

The words just quoted not only remind us of the innocence and idealism of youth, but make us ask ourselves why this should ever be spoiled or lost.

Many causes are behind the difficulties of the boy and girl at this period of life. For these causes parents and the adult world, with all its sins of omission and commission, are directly or indirectly responsible. We are not going to consider the abnormal child, the child of defective inheritance or development, abnormally precocious in the more gross sexual instincts or otherwise unbalanced, for he is a problem for individual treatment and does not concern primarily the management of the adolescent period. But while the period of adolescence is especially difficult for the neurotic child, it is also a time of strain for every child. This is the time of life when every organ and tissue is more rapidly growing and changing. Because of the maturing of sex characteristics, it is also the time when emotions of spiritual and religious significance with a half unconscious yearning to love and to be loved and a keen curiosity about the world in its relation to self receive a wonderful impetus; it is the climax in the history of man's slow and painful evolution into a being with a conscience repeated in the life of the individual. This is the time of awakened ideals which, if shattered, can never be resumed with the same zest; it is the age when the criminal is made and the foundation of failure or success is laid.

All of this we know in a general way, but do we know the child as an individual well enough to know what his or her special difficulties are? Do we know him so well that we are prepared to be a satisfactory consultant and to answer his questions so as to make him want to come to us for further knowledge? How many parents establish between themselves and their children a sympathy and understanding so strong that they are the first persons the child always wishes to consult when he is troubled by impulses to do what is contrary to the voice of his better nature? When these tender ideals and aspirations, these "sentimental" tendencies and

*Read before the conference of the Pacific Coast Social Hygiene Society, Berkeley, Cal., August 3, 1915.

strong friendships spring up, are they received and entered into with sympathy and encouraging direction along safe channels, rather than indifferently and hence allowed to be shattered by contrary influences in the world outside? How often at this most critical period of life the boy or girl is away at boarding school where even under the best conditions there are unhealthy influences at hand and no one to whom he or she can or will turn? Or if at home during this time how often the child and his friends are strangers to the parents when it comes to the inner workings of mind and soul!

Let us ask ourselves, why it is that we are so reluctant to speak of sexual matters and difficulties and to answer fully the many questions that a child will have answered in some way? It is not only because we are unprepared from lack of forethought, although that is in a measure responsible; but we are also shamefaced and mysterious toward these questions. Is it because we have an impure and faulty attitude of mind toward sex, because we have never fully realized the healthiness and holiness of the sexual instincts? Is there a hidden shame in our own hearts which we are unwilling to face frankly and readjust?

If all adults had for one generation realized the sacredness of sex relations and put this realization into practice, there could no longer exist the impurely suggestive drama, book, or newspaper item, or many of the other vulgarities for which we are now responsible because of our patronage, our morbid interest, or our tolerance; the subtle influences of the "red light" district and of "regulated" prostitution could not exist to excite the imagination of the young whose only playground is the street in many instances, nor would the idea that the young man must at all hazards sow his wild oats continue to undermine the ideals of us all.

We know very well that in the beginning the sexual instincts and the affections of children are pure and void of shame. If the subject of sex has become for them something to speak of in whispers or to be laughed at among themselves or otherwise degraded and distorted, whence comes such a state of affairs? It can only come by the suggestions of those older than they. Generally the first suggestion is in the form of ridicule of the child's friendship and attachment for some child of the opposite sex, or in the false modesty which is instilled into them by elders to whom any thought of sex is for some reason repellent. If we would purify or keep pure the minds of the young, our own mental attitude must first be sane and pure. We shall then have no difficulty in being frank and honest when discussing matters of sex hygiene with children. As we look back upon our own childhood and adolescence, we can recall that first thrill of joy akin to a highly spiritualized emotion which we felt when we first became particularly fond of one playmate in particular. There was nothing to be ashamed of or secretive about in this attachment, because the feeling aroused was one of boundless chivalry on the part of the boy and of unselfish fellowship on the part of the girl. But it was soon discovered that the grown folk were inclined to poke fun at such sentiment or else be distrustful of it, and this placed the first barrier in the way of future confidence between parents and child unless other barriers had long since been placed there by the indifference of elders toward the child's curiosity about the mysteries of life or by lack of real affection and mutual understanding. And so the child drew more and more into himself, and all the other ideals and aspirations and the energizing forces which were accompanying the awakening of the sexual instincts, were also kept to himself and found no expression in healthy ways. Such an experience may lay the foundation for introspectiveness, self abuse, or precocious sex experiences, because aroused energy will find some sort of an outlet.

THE CONSERVATION OF ADOLESCENT ENERGIES.

If this energy and the spiritual impulses which are part of its expression find no outlet away from self, the boy or girl becomes pitifully *blasé* in respect to feelings toward the best things in life. Few are the children who outgrow the impressions made upon them in early childhood, nor do they easily outgrow the effects of the suppression of the free development of mind and soul caused by misapplied punishment and unwise repression of activities.

How shall we prevent the too early stimulation of the physical part of the sex impulse, and how shall we best conserve and direct but not repress the mental, spiritual, and physical impulses which are aroused at this period? Finally, how shall we appeal to the child when he or she is already on the wrong path?

PREVENTION OF PREMATURE SEXUAL EXCITEMENT.

Here again we are confronted with the fact that in our modern world things which excite the physical senses, and especially the sexual instincts on their lowest plane, are thrust in the faces of our boys and girls. We allow this, and indeed we cannot easily prevent it. Our illustrated papers are read or seen in nearly every home, and often they contain stories or news items or so called jokes and pictures which, if not actually suggestive of immorality, at least tend to lower in the suggestible mind of the boy his respect for womankind, and in the mind of the girl the respect due to herself and to human nature. The same may be said of many of the theatrical performances that children are allowed to witness. Much the same sort of sexual stimulation may be found in the dress of adults and their social behavior; all this the adult world is responsible for, and in order to do away with these influences we must take our stand for the purification of the stage, popular literature, and social ideals, and so long as these are not in every way healthy things for the minds of adolescents to come in contact with, we must guard them against these things during the critical periods of their development.

But we must also supply entertainment of the right sort, for this they instinctively crave, and they welcome the beautiful and the good at this period, providing that they have not been led astray or unhealthily stimulated, or are not defective in moral sense and self control.

Recreation must be of the sort which allows the child to express his natural self. It must satisfy the

natural and innocent desire for friendship and companionship between the sexes, which becomes more keen at the adolescent period. This desire must be preserved on its originally high plane instead of being ridiculed by elders until the boy or girl becomes infected with a false modesty in relation to the opposite sex. Free, wholesome, and joyful companionship in work and play is a constant and absolute necessity. We have means of providing this in many children's organizations such as the Boy Scouts, the Camp Fire Girls, etc. All of these can serve to satisfy the idealism of youth as well as the need for physical activity, while the self indulgence and self absorption which are at the root of nervous disorders of the functional type will also be prevented.

DEFINITE TEACHING IN SEX HYGIENE.

We teach children many things; what do we teach them about the most important thing of all—life? What do we tell them about their own share in reproducing it and their own relation to the welfare of future human beings? What do we tell them about the sacredness and divinity of human bodies and minds? What about the unity and interdependence of all life? The romance and the sordidness of love and marriage are brought to the attention of boys and girls in many ways before they are out of their teens, but the beauty, joy, sacredness, and responsibilities of human relationships are seldom mentioned to them.

Instead of beginning when too late to teach the natural biology of sex in plant and animal life in schools, we need to teach the parent and guardian about these subjects, because it is to them that the child comes first with questions. If the child has had this foundation of knowledge given him by his parents before the period of adolescence, he will approach the more personal application of sex which he feels at puberty with a healthy viewpoint, and it will not be difficult then for parents to discuss such matters with him, for by earlier instruction and interest they will have acquired a natural and sane attitude themselves.

But this knowledge of biology and physiology and the respect for the wonderful nature of sex which such knowledge gives, is not all that will be necessary. Mere knowledge without a practical appeal to the moral faculty inherent in the child and so vigorous in the adolescent, will not avail in times of special temptation. The adolescent age is the time of sudden awakening of moral consciousness to its full measure, but primitive instincts are also carried over into this age, and between the two there is to be a constant struggle throughout life. We must therefore, at this time particularly, implant certain moral principles in the mind of the adolescent to which he may confidently resort in times of special danger. What appeals can we make which will either prevent or correct faulty sex hygiene?

First of all we can appeal to the respect due to one's own nature. We can tell boys and girls the truth about their physical nature—that it is something they hold in trust from their Creator, that they are made in his image, that their bodies are the temples of a holy spirit whose plan is a perfected universe in which there shall be no disease or abnormality, that they are the most wonderful mechanisms that have ever been conceived, and that for this reason alone they and the bodies and personalities of every other human being are sacred. We can tell them that their bodies and minds should be kept pure, because they are the agents for creating others like themselves to carry on the work and the ideals of the world. We can thus make the child want to be healthy in every way, not only from self respect, but in fair play to future generations. Those parents and teachers who are of the Christian faith can make more direct application of the doctrine of the incarnation of God in man.

We can tell children of this age that now is the time when their preparation for the function of parenthood is going on and that the boy is not being fair to the girl he may some day marry if he does anything to weaken his physique; and we can tell the girl that she is being unfair to the future mate and her future offspring as well as to her own nature. To both we can appeal on the ground of pride in bringing an untainted, wholehearted personality to the other. If young people of both sexes had a strong conviction of the sacredness of each other, could they in any way show disrespect for themselves or others? If, for example, the Christian lad had the same feeling for every girl and woman that he is taught to have for the Madonna, would not this feeling help him to distinguish between selfish lust and true love? And if the Christian girl could feel that she is a counterpart of the holy Mother, could she allow herself to sin against herself or to be sinned against? If all children had the same sort of respect for all humanity that they are apt to have for a wise and good father and mother, and were brought up really to reverence those who create life, would it not help their ethical relations later on? Can we make children reverence human life to this extent? We can if we have such a degree of reverence ourselves, and make practical application of our beliefs to the problems of social hygiene.

Nothing will appeal in times of temptation quite as much as the appeal to the instinct of hero worship, the appeal of loyalty to a personality, an ideal embodied in flesh and blood. This has been for ages the strongest incentive to right living. If the ideals of purity, health, and nobility of character are exemplified in those near at hand, those in one's own home or among one's comrades, so much the better; some have had to seek this example elsewhere, and for them, as indeed for all of us, the great personalities of human history, those both distant and at hand, continue to be available and to be a vital force in the world; for they bring Divinity very near to us. Can we not make a more practical study of these God-like and Christ-like personalities available for the adolescent in such a way as to make him eager to play his part well in hastening the spiritual progress of mankind?

Physicians' Building.

Industrial Accidents.—Dr. Francis B. Patterson, director of the State Industrial Safety Bureau of Pennsylvania, notes that industrial accidents during 1915 in the United States killed 35,000 persons, injured 300,000, and cost $250,000.

BOTHRIOCEPHALUS LATUS INFESTATION.

Report of a Multiple Case,

By A. I. Rubenstone, M. D.,
Philadelphia.
(From the Dermatological Department, Mount Sinai Hospital.)

While few cases of infestation in human beings with Bothriocephalus latus have been recorded in this country, it seems that this condition is growing more prevalent every year. This can be attributed to the fact that the vast influx of Europeans in the last two decades have brought enough of this parasite into the country to compel us to reckon with it, especially in investigating conditions among the foreign elements of our population. Cases have been reported by Walker (1), Leidy (2), Packard (3), Hagelstam (4), Reisman and Stengel (5), and McFarland (6). A brilliant report is that of Wilson (7). Edsal (8) remarks on the sparsity of reported cases.

It is a common affection among the peoples of nearly all the seacoast countries of Europe, especially along the shores of the Baltic Sea, in Germany, Russia, Norway, and Sweden. It is the tapeworm most frequently found in Japan and Ireland. The parasite is recognized with ease, its morphology being quite characteristic. The length of the full grown parasite varies greatly, from one foot to sixty feet. The head is the simplest in form of all the tapeworms, being oval in shape and very small, usually not exceeding 2.5 mm. in length and one mm. in breadth. Two longitudinal grooves provide the only means by which the head obtains suction. Following the head the tiny segments begin to appear, with very little intermediate substance to serve as a neck. Although the segments are very small at first and slightly longer than broad, they gradually increase in size, the breadth of the segment outstripping the length proportionately until the full grown segments are reached that are characteristic of the parasite. The segment is two to three mm. in length and ten to fifteen mm. in breadth. Occasionally imperfectly formed segments are encountered. The uterus is found coiled up in the centre of the segments, and when well distended with ova presents a rosette appearance. The color of the uterus varies from a light gray to a dark brown or black, depending upon the number of ova contained. The genital opening is discerned as a slightly elevated papilla arising from the centre of the uterus. The ova are elliptical in shape and quite large, many measuring over sixty microns in the long diameter. They are composed of a thin hyaline shell and a small lid at one end, through which the coarsely granular brownish contents may be easily expressed. The cysticercus stage occurs in fish, especially the pike. According to reported cases the parasite may give rise to no symptoms in the human host, or it may produce varying grades of gastroenteritis terminating in constitutional affections, chief among which is a form of severe anemia resembling pernicious anemia, which may prove fatal even after expulsion of the parasites. Constitutional nervous affections due to this worm, some of a very severe type, are recorded.

The following case is not only important from an etiological standpoint, but serves as an excellent illustration of the futility of attempting to diagnose vague clinical manifestations without the aid of detailed laboratory study, which so frequently is an excellent help in avoiding such meaningless statements as cryptogenetic, idiopathic, or neurasthenic in origin.

Case. The patient who first came under my care at the dermatological clinic of the Mount Sinai Hospital, October 2, 1915, was an intelligent Russian Jewish woman, fifty-one years of age, who complained of an itchy sensation over the entire body, especially severe over the lower abdomen and crural regions. This itch was of eight years' duration, sometimes subsiding for two or three weeks, but no longer, and always on recurrence at first very severe, especially at night, and gradually subsiding after five or six weeks, again to return with fair regularity. She had been treated by various physicians without material relief, and a few assured her that she had a nervous ailment, as they could detect no lesions at any time to account for her subjective symptoms. Physical examination revealed a cleanly, robust female, with a skin pale, moist, and warm, and the abdomen pendulous. There were scratch marks visible over several places on her body, especially the upper and inner regions of the thighs, and a few maculopapules were found over the body, especially on the lower portion of the abdomen. Otherwise she presented no visible lesions, nor did she recall having had a rash at any time. The patient appeared irritable and depressed. Specimens of morning and evening urine were examined and found negative. Blood sugar estimation was 0.11 per cent., which is within normal limits of glycemia. An internal sedative and a soothing external application were prescribed without influencing her symptoms to any degree. Upon her next visit, the complete blood count showed: Hemoglobin eighty per cent., red blood cells 4,210,000, white blood cells 10,200, polynuclears sixty-six per cent., small mononuclears twenty-two per cent., large mononuclears four per cent, eosinophiles eight per cent.

The eosinophilia was inexplicable, since the woman was in fair health and presented neither skin lesions nor a history of chest affliction to account for it. We therefore ordered a fresh specimen of stool following a saline purge, and were rewarded by finding the ova of Bothriocephalus latus in great numbers. The patient had lived in Riga, Russia, before she came to this country six years ago. She denied eating raw fish or engaging in that line of business. Upon close questioning she admitted having had several attacks of cramps and diarrhea in the last few years, which, however, were of short duration and did not apparently influence her general health.

We carried out the following course of treatment. The patient was starved for twenty-four hours, during which period only weak tea or water was allowed. Then she received the following prescription, which she took in one dose. Oleoresin of aspidium forty-five minims, tincture of vanilla forty-five minims, powdered acacia half a dram, and water enough to make one ounce. This was followed, one hour later, by fractional doses of calomel, one half grain each, until she had taken three grains. About eight hours afterward, she sent a knotted mass of tapeworm to the laboratory in a large dish. When unraveled, we found four worms which were easily recognized as the fish tapeworm. They were of the following lengths: Three feet 6 inches, 3 feet 8.5 inches, 4 feet 10 inches, and 5 feet 4 inches. Heads were found on all but the longest parasite, and a careful search failed to disclose it. Upon her next visit to the dispensary, the patient's symptoms had nearly all subsided, and within ten days had entirely disappeared, no ova could be demonstrated in her stool, and to date she has had no recurrence of symptoms, and seems to be in excellent spirits.

Since the completion of this paper, I have seen a

very good report of a case of bothriocephalus infestation by J. J. Singer (9), in which, however, castor oil was administered before and after aspidium in treating the case. He states that the patient was severely ill after the treatment. This can be easily explained on the ground that the oil caused the absorption of some of the male fern, which fortunately he had administered in fractional doses. It has been conclusively shown by Katamaya and O. Komoto, as well as Poulssen, that oils increase the absorbability of filix-mas and thus may lead to acute constitutional disturbances. It seems that calomel is especially efficacious in conjunction with anthelmintics, either because it directly affects the parasite or because of the increase in the flow of bile which follows its administration.

A CYSTOURETHROSCOPE FOR DIAGNOSIS AND THERAPEUTICS.

By C. Morales-Macedo, M. D.,
New York.

With the intention of uniting in a single instrument all the requirements of modern urethroscopic practice, I have designed along the lines of Geiringer's (1) device a direct view cystourethroscope, which is especially adapted for operative work. This instrument is so constructed that an operation can be performed either under a current of water or on a dry field, as the case may require.

In frequent use during the last few months, it has proved to give an absolutely true, slightly magnified picture of the trigone and neck of the bladder, and of the urethra, the entire circumference of which can be seen in one image. It is particularly serviceable in the fulguration of growths, in the therapeutic use of endourethral cutting instruments, and in making local applications. It consists of:

1. A straight endoscopic tube, seven inches long and No. 26 Fr. in calibre, with a slightly tunneled part and two faucets for double current irrigation;

2. An obturator provided with a freely movable beak;

3. A direct view telescope and a light carrier, which fit the tunneled part of the examining tube. The telescope slides in a special groove and can be withdrawn, leaving the light *in situ*;

4. A metallic plug, designed to close hermetically the proximal end of the sheath, while the telescope and light carrier are in. This plug is perforated for the passage of a fulgurating wire or any other suitable instrument. It can be removed when a dry intervention is planned; it can be capped with an unperforated rubber tip when only observation under running water is desired.

Technic for observation. The sheath, with the obturator *in situ*, is passed into the bladder. The obturator is withdrawn, and the telescope and light carrier are inserted. The metallic plug, provided with a nonperforated rubber cap, is properly fitted. An irrigator filled with sterile water, which is situated about three feet above the level of the table, is connected to one of the lateral faucets, and the flow is started. The other faucet is used to drain off the excess of fluid; it is advisable to attach to it a thin rubber tube dropped in a waste pail. The light is turned on and the telescope is moved slightly back to obtain the best possible distinct vision. The irrigation can be regulated to suit a thorough observation; when we desire to examine the distended canal, the discharging faucet must be closed, and when we need to bring about prolapse of the mucous membrane, irrigation is stopped momentarily.

We begin the examination of the practically empty bladder by inspecting the trigone and ureteral openings, which are clearly seen. By withdrawing the instrument, the circumference of the internal sphincter can be brought into view. The scrutiny of the prostatic urethra is now begun and the verumontanum is thoroughly inspected. The membranous urethra can be distended and examined. As the instrument is gradually withdrawn, the various parts of the anterior urethra appear successively in a view which ends at the meatus. It is possible to gain a distinct view of the entire circumference of the urethra in one image, provided there is not too much fluid distention.

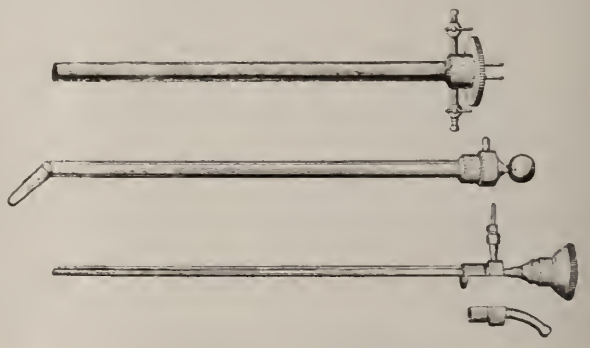

Fig.—Direct view cystourethroscope.

Fulguration and intervention under water current. A heavily insulated wire for fulguration can be inserted through the metallic plug, which is provided with a perforated rubber cap. The channel of this plug affords room enough for the passage of an instrument No. 12 Fr. in calibre; hence we are able to employ all the flexible instruments in common use for operation through a cystoscope. As running water is used, the operative work is done under the control of a clear field of vision.

Dry intervention. By the removal of the metallic plug, and cutting off the water supply, rigid instruments, such as applicators, urethral knives, curettes, probes, etc., can be carried through the endoscopic tube to meet the requirements of local applications and of some endourethral operations. Should magnification not be considered necessary, the telescope can be removed, leaving in only the light carrier, so the operator can take advantage of practically the whole lumen of the sheath.

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

DIET IN RELATION TO ACUTE AND CHRONIC ENDOCARDITIS.

By Louis Faugères Bishop, A. M., M. D.,
New York,
Clinical Professor of Heart and Circulatory Diseases, Fordham University School of Medicine; Physician, Lincoln Hospital.

The relation of diet to acute and chronic endocarditis is very important because in its ultimate analysis the heart is an explosive engine to which the food products supply the fuel.

The consideration of the heart as a machine is necessary for an analysis of its functions such as may lead to intelligent management. The simplest observation leads to the knowledge that the heart is an active mechanism and that it must be governed by the same principles that govern the operation of any other machine. Energy does not originate from nothing. We cannot conceive of the creation of energy. All we know about energy is as we see it transferred from one form to another. If we drop a stone from a height, the energy which is accumulated by the stone in falling is converted on striking the ground into other forms of energy, particularly heat. Again, heat may be turned back into motion, but there is no such thing as any beginning of energy. It always comes from some other form of energy, and as far as we know energy is never lost.

So the heart as a machine must obtain its energy from some place, from some matter, or some material, and in the production of energy that material must be used up. The heart seems very much like a gasoline engine. It operates by a series of contractions which represent an explosion, as it were, of accumulated force, just as the gasoline engine runs by the explosion of gasoline in its cylinders. The source of heart energy is found, of course, in its ultimate analysis in the explosion of food products, particularly in the explosion of derivatives from the carbohydrate part of the food. We know, in nutrition, the nitrogenous elements of food constitute what we might term the plastic materials of the body—the materials by which structure is built up, in the process of either growth or repair. On the other hand, the carbohydrates and the hydrocarbons, in uniting with oxygen to produce water and carbonic acid gas, produce heat and energy.

These in general are the functions of the two great divisions of food, the proteins and carbohydrates and fats, the fats being hydrocarbons. In addition to this the proteins have certain side actions which consist of stimulation and control of function. A person who is suffering from overingestion of carbohydrates may get fat and may have a great many disturbances of digestion and so on, but serious disturbances of functions do not develop, such as are found in the poisoning by over ingestion of nitrogenous foods.

The heart, therefore, is analogous to an engine which works through a series of contractions which are analogous to an explosion of energy.

The only rational explanation of the heart beat that anyone has ever elucidated has been that there is some particular substance formed in the heart between beats, which upon reaching a certain degree of accumulation explodes, as it were, and various considerations lead us to believe that when it is exploded it is fully used up, and must be reformed after each beat.

The older idea, that the heart contained certain material which was able to make contractions and that these contractions were instigated through nervous influence, has been dropped quite generally by students of cardiology.

When life is threatened in the course of heart inflammations, foods which are particularly capable of producing energy by oxidation are absolutely necessary. A few writers have even reported remarkable results from supplying sugar to failing hearts—perhaps on the same principle that a cook throws kerosene on a fire. These observations must have been made with a class of people who were already short of fuel foods because no such phenomenon has been duplicated in the author's experience.

The other point of view from which the question of foods in acute endocarditis may be considered, is that of their influence on the pathological process. From whatever angle this is approached, arguments will appear emphasizing the importance of the proper selection of the protein foods.

In chronic endocarditis the almost inevitable involvement of the kidneys, if by passive congestion alone, would indicate a limitation of nitrogenous foods to the actual needs of the body so as to spare these organs from overwork.

Also, we must mention the frequent association of chronic endocarditis with gouty conditions in which the metabolism of urea is disturbed, leading to the formation of uric acid and sodium urate.

In many persons suffering from endocarditis there is a mechanical passive congestion of the liver that limits their capacity to deal with foods which—in popular language—tend to produce "biliousness"; in other words, very rich foods.

A very great question in cardiac patients is how to deal with the symptoms due or attributable to gases in various parts of the gastrointestinal tract.

This is a subject almost coextensive with the practice of cardiology, and the solution of it pertains as much to the art of medicine as to the science of the vocation. The man who jumps to the conclusion that this consists *merely* of a fermentation of carbohydrates is very, very wrong; equally so the man who attributes it to the purely local digestive disorders. It is a symptom often enough of reflex nervous origin pertaining largely to the defective function of the liver depending upon the circulatory disturbances of passive congestion or high blood pressure. In proportion as the cardio-

vascular disease is relieved, the symptom becomes less troublesome.

Out of door exercise is probably the best single remedial measure. The deprivation of the cardiac machinery of its necessary carbohydrate fuel, with the idea that this may ferment, in the long run leads to the ingestion of too many proteins and interferes with recovery from the cardiovascular disorder.

The principle involved in the dietetics of a person suffering from a heart defective on account of endocarditis is thus seen to be clarified by appreciation of its analogy to an active mechanism. An automobile engine is a hydrocarbon engine; the heart is a carbohydrate engine.

Proteins may act as stimulators of the heart and in minute proportion they may go to build up structure, but it is the fuel foods that supply the energy. Therefore, in proportion to the proper adjustment of our fuel supply, both in quantity and in mixture, will be the length of time during which satisfactory action may be expected.

54 West Fifty-fifth Street.

Antimony in Foods.—Poisoning of mysterious origin is doubtless more common than is generally appreciated. By this, remarks the *Journal A. M. A.* for September 16, 1916, we do not refer to the obviously profound effects of large doses of highly deleterious compounds, but rather to the more subtle intoxications of a mild grade which often escape notice because of the unexpected ways in which they may arise. Industrial poisonings are occasionally of this character. Recently we called attention to the possibilities for harm in the accidental employment of daffodil bulbs as food.[1] Some time ago the warning of the Hygienic Laboratory of the United States Public Health Service against the use, for milk bottles, of rubber nipples containing antimony was mentioned.[2] Recently unexpected possibilities of harm have been detected in some of the enameled cooking utensils that are sold in American markets.[3]

When these dishes first becan to supplant crockeryware, considerable agitation arose in Europe regarding the possibility of lead poisoning from food prepared in dishes highly glazed, because this metal is employed in the arts in which glazing is carried out. In the case of sheet steel enameled ware, for which a glaze of great brilliancy is not required, it has been possible to use other substances to act as a flux. It is now widely believed that lead is not used in the manufacture of popular enameled dishes. Investigations by Miss Miller[3] at the University of Chicago indicate that this element was liberated in exceptional cases only, by vigorous cooking tests with enameled dishes of standard make.

Not so with antimony, however. This relatively cheap substance has long been added to certain enamels to make the glaze opaque. Usually tin oxide is employed. Arsenic is said to be used only in enamels for decorative purposes. Presumably enamels containing antimony can be made so resistant to mild chemicals that practically none of the poison will dissolve in the ordinary cooking process. Nevertheless, some of the European countries have forbidden the use of antimony in culinary utensils. No such prohibition exists in America. Miss Miller has recently found that some antimony was dissolved in every case after cooking various foods in cheap gray enameled kettles purchased in certain stores where the poorer classes trade. As an illustration of the quantities liberated in this way, acid substances like grape juice, cider, and cranberries acquired from three to fourteen mg. during a cooking test. A serving of spinach incorporated nearly ten mg. of antimony from a small dish. Even fresh milk dissolved out three mg.

Various factors seem to influence the amount liberated. The acidity of the foods, the number of times the dish has been used, the amount of abrasion in the culinary process, temperature, and a time factor doubtless all play a part. Miss Miller remarks that the fact that one make of enamel is so readily attacked as to betray its inferiority by the abrasion produced would probably prevent its use by intelligent persons; but the less intelligent might adopt it without question. The toxic dose of antimony is not so large—the average dose of tartar emetic contains only five mg. of the element itself—that its introduction into foods through the medium of cooking utensils can be overlooked. Further investigation is desirable in the interest of public health.

Hypertension, Interstitial Nephritis, and the Diet.—An editorial writer in the *American Journal of Electrotherapeutics and Radiology* for July, 1916, points out, referring to the hypertension with arterial changes often associated with interstitial nephritis, that the more recent scientific investigations have shown that hypertension precedes the structural changes both in the kidneys and the arterial system. Persistent hypertension is thus considered to be the primary cause of these structural changes. The actual cause of this hypertension, furthermore, is held to be in many cases an excessive decomposition of proteins in the bowel. The professional mind is turned away from the old theory of the uric acid diathesis, the presence of uric acid being itself similarly due to an excess of protein in the diet. The paramount indication in hypertension thus lies in correcting the diet and in anticipating the protein decomposition processes in the colon through timely evacuation of the bowel contents. Such procedures bear the same relation to the administration of lactic acid bacilli as prophylaxis does to an antidote, and it becomes a question whether the longevity in certain Balkan peoples ascribed by Metchnikoff to the consumption of sour milk, is not due rather to a simple and relatively restricted diet. The fact that arteriosclerosis is rapidly increasing in the United States compares significantly with the steady rise in the per capita consumption of animal food in this country. Reeducation of the public mind in this direction is thus a matter of the first importance from the standpoint of prophylaxis. In respect of advanced hyper-

[1] Poisonous Properties of the Garden Daffodil, *Journal A. M. A.*, July 22, 1916, p. 290.

[2] Bull. 96, Hyg. Lab., U. S. P. H. S., 1914, p. 56. Rubber as a Source of Hygienic Danger, *Journal A. M. A.*, Nov. 28, 1914, p. 1954.

[3] Elizabeth W. Miller: The Solution of Antimony from Enameled Cooking Utensils, *Jour. Home Econ.*, viii, 361, 1916.

tension cases in which arteriosclerosis and nephritic changes have already developed, the impression has been prevalent that the high blood pressure in these cases is compensatory and should not be lowered. This is entirely disproved by the experience of numerous observers. On the contrary, measures to lower the pressure, including a meat free diet and treatment calculated to improve the hepatic and renal functions, should be taken, for under such treatment casts and albumin disappear from the urine and vascular tension is readily kept below the danger point. The static wave current is of great utility in lowering the blood pressure and coincidently ameliorating the renal condition.

The Rice Diet: How to Prepare It and How to Eat It.—H. S. Bartholomew (*Medical Record*, August 19, 1916) states that this diet consists of rice, butter, bread, water, and salt with absolutely nothing else. This is taken three times daily at regular meal time and eaten hot with a fork, at least half an hour being consumed at each meal. No cream, milk, or sugar is to be used, while water is to be taken at each meal, but not while rice is in the mouth, as it interferes with the action of the saliva on the rice granules. Water should be freely consumed between meals, and at least four ounces of butter must be taken daily. The preparation of the rice is important; five tablespoonfuls of rice are boiled thirty minutes in two quarts of water without stirring; after straining and allowing to stand for a few minutes to dry, it is eaten hot.

[Proper selection of rice is of prime importance. The natural or brown rice is preferable to the talcum coated or polished rice usually sold. Natural rice is not only of much higher nutritive value, but is far more appetizing.—EDITORS.]

The Dietetic Treatment of Round Gastric Ulcer.—A. I. Iarotsky (*Roussky Vratch*, June 4, 1916) maintains that gastric ulcer can be cured by diet alone, but the diet must contain a sufficient number of nutritive elements, and yet be so bland that it does not stimulate the secretion of gastric juice. It must leave the stomach quickly and be digested largely in the intestines. Egg albumin, olive oil, or unsalted butter fulfills these requirements better than any other food. The white of eggs not only leaves the stomach rapidly, but possesses the additional advantage of combining with the free hydrochloric acid which may be present. The whites of about eight eggs should be mixed with water (not beaten up) and given in the morning, and 160 grams of butter in the evening. This diet contains about 1,200 calories. No water or ice is given by the mouth, thirst being allayed by the use of enemas. To the latter may be added small amounts of sugar. The diet is kept up for ten or twelve days, when carbohydrates are added in the form of potato purée, with butter, rice, barley, or farina soup; later, fresh ground vegetables with butter. On this diet patients may be maintained for weeks and even months. This treatment, according to the author, allays pain, gastric distention, and eructations, rendering the use of drugs unnecessary. The drugs usually employed in the treatment of gastric ulcer are worse than useless. Morphine, for instance, following a temporary inhibition, increases gastric secretion. Atropine has a similar action and, besides, exerts an undesirable systemic effect. Nitrate of silver, the old standby in the treatment of gastric ulcer, is distinctly contraindicated because of its stimulation of gastric secretion. Subnitrate of bismuth is harmless and may be employed.

The diet recommended by the author is indicated also in toxic gastritis, hyperchlorhydria, and after operations on the stomach.

Food Causing Renal Disease in Soldiers.—Albert Albu and Erich Schlessinger (*Berlin klin. Woch.*, February 7, 1916).—A wide experience with so called trench nephritis seems to show that exposure to moisture and temperature fluctuations has little etiological relation to the condition. There is, further, no evidence of an infection being the underlying cause. Only one common factor could be found, namely, an altered and unbalanced diet. Under war conditions the men receive a diet deficient in fresh vegetables and fruits, low in fats and meats, the majority of which are salted or otherwise preserved. It is suggested that this diet is largely deficient in the necessary vitamines and that its continued use gives rise to a toxic state which damages the kidneys and causes an acute nephritis.

Dietetic Management of Hypercholesterinemia in Cholelithiasis.—M. A. Rothschild and N. Rosenthal (*American Jour. Med. Sci.*, Sept., 1916) divide cases of cholelithiasis into those with normal cholesterin content of the blood, and those which are hypercholesterinemic. The latter is subdivided into the obstructive and the diathetic, and is the only group considered. The object of treatment is to reduce the cholesterin content of the blood, which may be secured by diminishing the cholesterin content of the food, and by rendering the absorption of cholesterin as difficult as possible. These two conditions can be satisfied by placing the patient on a fat free diet, which both excludes lipoids to a large extent, and renders difficult the esterization of the free cholesterin in the food. Our foods in general are poor in cholesterin esters. Eggs, cream, butter, meat, and fish are excluded, as they are rich in lipoids. On a strictly lipoid free diet only vegetables are allowed, excluding beans and peas, which are fairly rich in phylocholesterin. All other vegetables, as well as cereals and sugars, are allowed. Milk should be skimmed and fat free buttermilk permitted. This diet is so strict that the majority of the patients will not maintain it for a long period, so "fast and feast day periods" have been devised. For three or four days a week the patient lives on the strict, lipoid free diet, which serves to deplete the organism of the stored up lipoids. For the next three or four days, depending upon the grade of the hypercholesterinemia, he is allowed, in addition to the vegetables, well cooked lean meats and fish, excluding salmon, shad, and bluefish, the fat content of which is high; oleomargarine is allowed in place of butter. The writers promise to publish a report of the permanent effects of this treatment in their cases, which have not been under observation long enough for such effects to be determined.

Contemporary Comment

Discords.—Under this heading, H. G. W., an editorial writer in the *Long Island Medical Journal* for September, 1916, bursts into gloomy lyrical numbers as follows: On the hottest night of summer, when there's not a breath of air, when no fan will lure the coolness of old Zephyr from his lair, and you sit in dripping misery apraying for a breeze, what is that which gently agitates the leaves upon the trees? It's the pianola thumping from the house across the street, while the lamplight shows the player and his madly prancing feet. And deep sympathy is added to the perspiration's woe; not for the cussed player, but the tune he's mangling so. Then you seek another window as far as far may be from the ragtime irritation of the fiend who's made you flee. But the music teacher's practising her never ending scales and her exercises punctuate the tom cat's hideous wails as they rise in deafening unison from fence and first floor back and your tortured nerves are stretched so taut it seems that they must crack. And the phonograph three doors away is playing shrill and thin the *Rocky Road to Dublin* or that *Tipperary* thing, while your neighbor's baby calls its Ma to find some torturing pin. The city in the summer's full of music's flats and sharps, full of auto horns and wagon wheels and licensed canine barks; full of shrieking trolley car brakes and the shrill street vendor's cry; so if you're seeking peace on earth just pack your duds and fly.

The Physicians' Opportunity.—The physicians in every city, town, and village should avail themselves of the opportunity to bring home some forceful truths to the laity, at this time. The people are in a mood to listen and to act. Just at present all eyes are upon New York and the people are dreadfully worked up over the fact that 1,260 persons (mostly babies) have died of infantile paralysis since January, 1916. This is a waste of precious life and a condition to be deplored.

But why not call the attention of the people now that they are awake and in a listening attitude, asks the *Texas Medical Journal* for September, 1916, to the fact that diphtheria, scarlet fever, typhoid fever, measles, and whooping cough are much more dangerous as causes of death than infantile paralysis? Tuberculosis is many times more important than infantile paralysis, both as regards the amount of sickness it causes and the number of people it kills. The people should be convinced that typhoid fever need not exist at all if all that is known about it were actually utilized.

The bubonic plague of today is identical with the black death of the middle ages. It is estimated that every case of human plague costs the municipality in which it occurs $7,500. It is well known to physicians that rats are the carriers of the pest bacillus, which occurs in three forms, viz., the pneumonic, with a death rate of almost 100 per cent.; the septicemic, which is nearly as fatal, and the bubonic, which claims fifty per cent. of its victims—but are the people making war on rats? Would they want these pests in the home if they could be made to understand how great the danger? There is absolutely no excuse for the existence of the fly, the mosquito, the rat or mouse, and a number of other things not mentionable in polite society. If the general public could be awakened and kept awake long enough to become convinced and aroused to these facts what a cleaning up there would be. But there must be "line upon line and precept upon precept," and it is greatly to be feared that until the end of time we shall have these unwelcome, obnoxious pests among us.

Poliomyelitis to Great Britain via Canada.—Some alarm as to the possibility of an outbreak of infective poliomyelitis in this country is not unnatural in view of the epidemic from which New York is at present suffering. Transit from America nowadays is very rapid, and if the disease should spread to the training grounds in Canada, we might be subjected suddenly to a terrible outbreak among our soldiers. Both as sanitarians and as physicians we are peculiarly helpless in face of infective poliomyelitis, observes the *Medical Press and Circular* for August 30, 1916. We do not know the organism, and we know little of its manner of infection. The organism appears to be present in the nose, throat, and intestines of the affected subject, but as to the manner of carriage from one patient to another we know little. It is a summer disease, and dust has been blamed as the infective medium. Flies also have been supposed to carry the infection, but at present the favorite theory is that of the human carrier. It is supposed that a human subject may be infected as to the mucous surfaces without the spinal cord suffering or symptoms being caused, and that he may give the infection to those with whom he associates. In view of this uncertainty as to the mode of spread, American sanitarians are reduced to the medical precaution of quarantine, and it is likely that similar precautions will have to be adopted here toward travelers from infected areas.

Compulsory Health Insurance.—In this delightfully cool season with the daily temperature seldom running over 95° F. in the shade, we crave treatment by acupuncture or something equally soothing. We get this treatment fortunately, from time to time, from self constituted legislative Solons whose panacea for social misery is that every worker shall be compelled, whether or no, to insure his health. "Compulsory health insurance," their rapid fire typewritist assures us, "is the *only* means for checking the lowered vitality and the poverty created by present day conditions!" He adds persuasively, "that this system of health insurance for a small sum divided among employer, worker, and State, will bring medical care to the wage earner and his family, will assure for a maximum of twenty-six weeks in a year, a weekly payment of two thirds of wages during the bread winner's illness and in additionally (*sic*) a small funeral benefit should he die." "Compulsory health insurance is an economical means of providing adequately for the sick wage earner and will prove a mighty force for the inauguration and of a comprehensive campaign for health conservation."

We doubt whether even in cool weather the American working man will care to be Prussianized by these altruistic friends of the people.

THE CLEARING HOUSE IDEA FOR MENTAL DEFECTIVES.

The menace of the army of the feebleminded and the otherwise mentally deficient has been brought so near to the public and to the profession that the work of identifying them, keeping them under surveillance, and treating them has progressed rapidly. Beside being an economic burden on the community, the mentally deficient are criminals and social outcasts in embryo, and prolific propagators of generations of like kind. For those whose mentality is low, crime is the path of least resistance. Necessarily, to be of much constructive value, the detection of the defective element in society must take place in early life, before damage of this nature has been accomplished. The exclusion of alien foci of feebleminded strains is rapidly being controlled by the Public Health Service. The large number of the certified mentally defective is ample illustration of the reality of this condition among aliens and quite justifies their exclusion. Experience in the rapid examination and diagnosis necessarily developed in handling the vast throng of immigrants will be of untold value in carrying on this work among native classes on a large scale.

Until recently, however, little has been done to detect and to treat mental deficiency among school children, except to relegate backward children to special classes. Very few extra or reinforced methods of training were put into use. To be sure, the defective child was allowed a much longer time to learn than the normal child, but the main purpose—none the less a good one—of the separation was to put the defective where he would not impede the progress of apparently normal children. The wait for the end of the school period, when the unfortunate could be legally shooed out of school and into the world to take his place among the human derelicts, was always an impatient one; and the medical inspection of school children, while in vogue for a comparatively long time, was directed toward the conservation not so much of the child's mental as of its physical condition. Now, however, most enlightened school boards are beginning to introduce systems of special examinations to determine, to separate, and to treat the mentally feeble. The systems are still in the experimental stage; only children whom the teachers consider particularly defective are referred, and not every child receives the benefit of examination.

Modern principles of schooling require intelligent appreciation of impediments to learning rather than of special aptitudes of the school child. Children's abilities and taste change rapidly, even from month to month, and attempted vocational guidance is of illusory value; it is always feasible, however, to detect and often to remove obstacles to growth. As a condition of progress in school grades the child should be examined by the psychologist to determine incapacities. No psychologist or psychiatrist can measure even approximately the latent possibilities of most children. Probably the majority of the leading originating minds of the world have been backward students while at school, retarded by the deadening routine and inflexibility of conventional school methods. It is quite possible for the school registration desk, when properly organized and conducted, to become the largest, most thorough, and most efficient aid in ascertaining causes for mental retardation, and thus lessen waste of the public funds and of the child's time.

In the absence of this method, the clinical clearing house idea is a good temporary substitute. The clearing house receives all suspected persons for diagnosis and treatment. A record is kept and cases are followed up. In order to increase the number coming under the influence of the clearing house, large employers of youthful labor should be urged to send their employees and prospective employees

through the clearing house. This proceeding alone would tend to reduce the industrial accidents. We cannot help feeling when in contact with those engaged in the simple and automatic occupations in large factories and packing houses, that they are good for little else, and that in some way and to some extent, they are defective. Proper training after clearing house diagnosis would serve to rehabilitate many of them.

The main value of the clearing house idea as a force in preventive medicine lies in determination of the nature and the degree of deficiency, the presence of some patent faculties, and their amenability to training for some vocation. The removal of mental disabilities does more to develop the social idea and to discourage the antisocial tendencies so prominent in the criminal defective, than any other factor.

But the most comprehensive project for the determination of the incidence of the mentally defective among the general population, and the determination of the best methods for combating this evil, has been undertaken on a large scale by the National Committee for Mental Hygiene under the directorship of Dr. Thomas W. Salmon. It is the clearing house idea on a national scale; under direction mental surveys are being carried on wherever possible, and before long the result will be a crystallization of the knowledge on this subject, while attacks thereon will be conducted more scientifically. The whole subject, the work of this committee in particular, deserves the encouragement and the support of the public, especially of the medical profession.

THE COMPLICATIONS OF RENAL TUBERCULOSIS.

Tuberculous cystitis is the necessary consequence, the first complication of renal tuberculosis, and by itself alone reacts intensely on the patient's general health. Surgical interference, such as a cystotomy, will have a tendency to improve the vesical lesions and by placing the organ at rest the severe and constant pain is done away with. The excellent results of this operation can hardly be overestimated.

The tuberculous lesions of the ureter produce stricture resulting in stagnation of the urine above. The importance of these lesions in renal tuberculosis is great, yet they are often overlooked. A pyonephrosis thus set up may be purely tuberculous, or on the other hand, be due to a secondary infection. In the latter case the clinical picture may very likely be that of an ordinary nontuberculous pyonephrosis.

This dual infection may also take place in the perirenal fat and the presence of tuberculous lesions can be demonstrated, although it may appear healthy and play an important part in fistulæ following nephrectomy. Koch's bacillus may produce true cold abscess in the perirenal fat, and such collections must not be mistaken for abscesses having their starting point in the ribs or vertebræ. These abscesses are sometimes the first evidence of renal tuberculosis, but in most cases they are due to a secondary infection, particularly by the colon bacillus, the organism reaching the perirenal fat by way of the blood or lymphatics. The evolution of these perinephritic collections is most variable. As they usually extend downward toward the abdomen they may simulate an appendicitis or open into some hollow viscus or even through the abdominal wall, when the resulting fistula remains permanent.

The extension of the infection toward the thorax is less common, although cases have been met with, and the real origin of the pleural or pulmonary suppuration will be difficult to detect. Pleurisy during a renal tuberculosis is not uncommon, and a careful history of the case will often reveal this lesion in the patient's antecedents before the renal lesion has given rise to any symptom. In this case the pleurisy will usually be on the same side as the affected renal gland. A bilateral infection of the kidneys, at least at the beginning of the renal process, is relatively rare and is a great handicap to surgical treatment. When the lesions are of mild degree in one kidney, however, it is well known that an operation on the severely diseased renal gland may produce a great improvement in the patient's health.

TUBERCULOSIS IN THE BRITISH ARMY IN FRANCE.

Perhaps the most remarkable and, from the hygienic standpoint, the most satisfactory feature of the European war has been the comparative absence of epidemics which in former wars have wreaked more devastation in the ranks than shot and shell. Enteric fever, in particular, has been rare and the control of what may be termed war epidemics has been a triumph for efficient sanitary measures properly enforced. As to the incidence and prevalence of tuberculosis among the soldiers of the allied armies on the western front, accounts have been somewhat confusing. The statement has been made more than once, that there has been little tuberculosis in the French and British armies, that many tuberculous cases were benefited by the outdoor life which these fighting men perforce had to lead. While in some instances, however, the course of tuberculosis may have been arrested by the conditions of living, it is hard to believe that trench life and the fearful hardships which those

at the front had to endure, can have exerted a wholly favorable influence. Sir William Osler, on July 26th, delivered an address at the annual meeting of the National Association for the Prevention of Tuberculosis, taking as his text the tuberculous soldier. He pointed out that pneumonia and tuberculosis had levied the heaviest toll among the British soldiers, and predicted that when the mortality statistics of disease were published from the army of the west, the "best killer" would be found to be the pneumococcus, a home bred germ which the soldier takes with him or catches easily from a comrade. With regard to tuberculosis and its martial relationship, Osler made three preliminary statements: 1. In a majority of the cases the germ enlists with the soldier. A few, a very few, catch the disease in infected billets or barracks. What percentage of the men is infected is not known, but it is exceptional not to find traces of tuberculosis in the bodies of men of the enlistment age, who died of other diseases. 2. Of one million enlisted men of the age aforesaid the proportion to acquire tuberculosis is probably much smaller than if these men had remained in civil life. It will be possible later to work out the exact incidence for comparison with figures already available; but the circumstances of the soldier's life, as a rule, do not weaken, but strengthen resistance. 3. Exposure, hardships in the field, injury, drink, and syphilis may bring about favoring conditions for bacilli which already exist or which may gain access to the patient, and the soldier reports sick with tuberculosis of lungs, glands, pleura, bones, or brain.

It is evident that tuberculosis is prevalent in the British army in France, which may be explained, to a great extent, by the lax methods of examination. Until conscription was enforced, men were so badly needed for the army that the medical examination was not very searching; consequently, many doubtful cases were let through. Under the strenuous life which is the lot of the soldier today, it is no wonder that those who were infected with the tuberculosis germ, were unable to stand the strain. A soldier's life is not indicated for those who are so tuberculous as to be unable to pass a searching medical examination. However much fighting material may be required, to enlist doubtful cases on the supposition that they may become hardened involves too great a risk.

SYPHILIS AND DIABETES.

Syphilis has been called upon to explain many of the aches and ills of mankind, and has, in the large majority of instances, been obliged to plead guilty to the indictment. One of the most interesting possibilities of causal relationship at the present time is that which may exist between syphilis and diabetes. Ever since Opie first began his investigations, it has become an accepted tenet that the latter disease seems very commonly to follow the transformation of the vascular islands of Langerhans of the pancreas into fibrous tissue. As to the ultimate cause of this lesion little, if anything, definite has been determined, and yet that is essentially the crux of the matter.

In Osler's *System* Futcher states that in occasional cases diabetes may be traced to a syphilitic infection, but that these cases are undoubtedly rare. He holds that when syphilis plays a part, the lesion is most likely to be a local one, most probably situated in the region of the medulla or pituitary gland. He adds, however, that nutritional changes in the brain and pancreas from syphilitic arterial disease must be considered as a possible cause.

Treponema has been found in fibrous pancreatitis of the intraacinous type accompanied by diabetes. It has not as yet been proved, however, that syphilis is the common cause of diabetes, but it evidently plays a very important role at times. A Wassermann reaction in every case of diabetes might go far to establish the relationship between these two diseases.

Another point of interest is the so called diabetic gangrene that occupies so prominent a place among the complications of diabetes. To quote Futcher again, "The artery supplying the affected area shows arteriosclerosis in the vast majority of cases." That this is the underlying lesion is stated by both pathologists and clinicians, yet the possibility of syphilitic infection being at the bottom of the trouble is nowhere mentioned. A careful microscopic study of the tissues might reveal the presence of treponema.

It would appear that, although syphilis may not be the cause of every case of diabetes, yet the combination of the two diseases occurs more commonly than is suspected. Consequently it behooves the physician to do more than make a mere urinary examination; a Wassermann reaction may assist materially in determining the diagnosis, and thereby give a clue to the treatment.

A LETTER FROM HOT SPRINGS, ARK.

An old and valued acquaintance, Dr. Loyd Thompson, of Hot Springs, Ark., in a personal communication, complains that some remarks of his made at the Detroit meeting of the A. M. A., on the intensive treatment of syphilis, were somewhat garbled in their publication abroad, and asks if we cannot help set him right in the eyes of his confrères. Doctor Thompson was accused of stating that he used metallic mercury intravenously in one gram

doses—Heaven help the patient! the doctor ejaculates piously. Another accusation was that he injected mercury intraspinally. Furthermore, the impression was conveyed that the doctor did not believe in the waters of Hot Springs for the treatment of syphilis—a most unlikely belief, we think, in a resident.

To cite the doctor's own words in refuting these ridiculous statements: "This certainly is a mistake, as I do believe such bathing to be of decided benefit in the treatment of this disease. I do not consider the waters of the hot springs as possessing any treponemacidal properties, but it is a fact that the majority of patients bathing in these waters can tolerate much more mercury than those not bathing. It is also a fact that these baths cause an increase in the elimination of the products of catabolism, which undoubtedly is of direct advantage in the treatment of syphilis. Added to these direct advantages the syphilitic who is treated in Hot Springs usually is free from business worries, leads a regular life, participates in outdoor exercise, and finally, the average patient who comes to this or any other resort follows the physician's directions more implicitly than when at home; in short, makes a business of getting well."

AUTOTHERAPY IN IVY POISONING.

Dr. J. M. French, of Milford, Mass., reports in *Clinical Medicine* (August, 1916) remarkable results in the prevention and cure of rhus poisoning by chewing the young leaves of the plant and swallowing the juice. The simplicity of the remedy certainly commends itself, though until more reports are made it would hardly be well to advise patients who have not been infected to look for the poison ivy plant so as to use it for prophylactic purposes. Remembering the nature of the cutaneous lesion of rhus, recipients of this oral prescription are likely to suspect a practical joke and to imagine themselves with very sore mouths. The remedy, however, seems to be in perfect accord with the theory and practice of Dr. Charles H. Duncan, who will pounce on this case report as a fine example of his beloved autotherapy.

EFFECTS OF DEPOPULATION IN FRANCE.

At a meeting of the Académie de médecine on August 1, 1916, M. Debove (*Paris médical,* August 19th) presented a pamphlet from the pen of M. R. Lépine, of Lyons, in which it was proved that if the French birth rate had equalled the German since 1870, France today would have a population of seventy millions. On the other hand, if France wins in the present war and the birth rate does not improve, victory will be of no value to her because she would be unable to resist future German invasion. The author of the pamphlet lays stress on the absolute necessity of bringing strong and healthy children into the world, quality being an important corollary of quantity.

Obituary

SIR THOMAS LAUDER BRUNTON, Bart., F. R. S.,

of London, England.

Sir Thomas Lauder Brunton died in London, on September 16th, in his seventy-third year. He was born in 1844 and educated at the universities of Edinburgh, Vienna, Berlin, Amsterdam, and Leipsic, receiving his degree of Doctor of Medicine in 1868. Subsequently he had conferred upon him the degrees of Sc. D., by Edinburgh in 1870, and M. D., by Dublin in 1908; the F. R. C. P. he had achieved in 1876. Sir Thomas was consulting surgeon to St. Bartholomew's Hospital, London, and until lately was lecturer there on pharmacology and therapeutics. He was a copious writer on medical subjects, his principal work being the *Handbook on Pharmacology, Natural Medicine and Therapeutics,* an edition of which became popular in this country on account of its listing the preparations of the U. S. P. as well as the British. Sir Thomas was knighted in 1900 and became a baronet in 1908. He was vice-president of the Royal Society.

ADONIRAM BROWN JUDSON, A. M., M. D.,

of New York.

Doctor Judson died at his home, 53 Washington Square, on September 20th. He was born in Maulmain, Burma, in 1837, his father being an American missionary in that country, and after his preliminary education took the A. M. at Brown University in 1859. He then studied medicine at Harvard and Jefferson, obtaining the M. D. from the latter in 1865, and an *ad eundem* from the College of Physicians and Surgeons, New York, in 1868. During his earlier medical studies the Civil War broke out, and Doctor Judson became successively assistant surgeon and surgeon in the United States Navy. At the conclusion of the war he began practice in New York and soon became identified with orthopedic surgery. He was an inspector of the board of health until 1877 and an examiner for pensions till 1884. From 1878 until 1908 he was orthopedic surgeon to the outpatient department of New York Hospital. In 1891 he was president of the American Orthopedic Association. Doctor Judson was the author of several medical works and a frequent contributor to the New York Medical Journal, being a consulting member of the editorial staff in orthopedic surgery and matters of public health.

News Items

Woman's Medical College of Pennsylvania.—The opening exercises for the session of 1916-1917 were held by this college on Wednesday afternoon, September 20th. Dr. Albert P. Brubaker, professor of physiology and medical jurisprudence, Jefferson Medical College, Philadelphia, delivered the address.

Silliman Lectures.—These lectures will be given in the Lampson Lyceum, Yale University, at 5 p. m., Monday, Tuesday, Thursday, and Friday, October 9th to 13th, by J. S. Haldane, M. D., LL. D., F. R. S. The subject of the lectures is Organism and Environment as Illustrated by the Physiology of Breathing.

The Opening Exercises of the College of Physicians and Surgeons, Columbia University, for the academic year 1916-17, will be held in the lower lecture room, Wednesday, September 27th, at 10:30 a. m. After a brief address of welcome by President Nicholas Murray Butler, an address will be delivered by Dr. Warfield T. Longcope, Bard professor of the practice of medicine, on Milestones in Medicine.

The Naval Medical School will open at Washington, D. C., September 29th, with eighteen students. The assistant surgeons, Medical Reserve Corps, who compose the class that will enter the school at that time are L. D. Arbuckle, Franklin T. Bower, Julian C. Brantley, A. H. Cecha, Theodore E. Cox, Carroll H. Francis, James A. Halpin, Arthur W. Hoaglund, Lincoln Humphreys, Irving W. Jacobs, Harold L. Jensen, Ogden D. King, Aubrey M. Larsen, J. J. Laughlin, Franklin F. Murdoch, P. F. Prioleau, Arthur C. Siston, Jr., and Louis H. Williams.

Personal.—Dr. Louis Heitzman, of New York, has been appointed professor of pathology and bacteriology at Fordham University School of Medicine.

Dr. L. D. Bristol, a graduate of Johns Hopkins University, formerly a member of the faculties of Minnesota and Syracuse Universities, and for the past two years professor of bacteriology and hygiene and director of the State Public Health Laboratories at the University of North Dakota, has accepted the newly created Boston Dispensary Fellowship in Public Health in the Department of Preventive Medicine at Harvard Medical School, Boston.

Influence of Occupation on Health during Adolescence.—Massachusetts is now engaged in a systematic effort to collect information that may be of value in determining the need of changes in its present laws and regulations governing the employment of minors. At the request of the Massachusetts Board of Labor and Industries, Assistant Surgeon M. Victor Safford, of the United States Public Health Service, was detailed by the Federal Government to cooperate with the State authorities in a study of the effect of employment in various occupations on the health and physical development of children now permitted by law to work therein. A report of this study, with respect to the cotton manufacturing industry in Massachusetts, has just been published by the Federal Government as Public Health Bulletin No. 78. This bulletin shows that in Massachusetts boys between the ages of fourteen and sixteen for the most part do not remain long in the cotton mills. Evidence of injurious effects on normal boys of their work or working conditions was seldom found, and few cases of dangerous diseases were discovered. There was, however, a wide variety of defective conditions disclosed by the investigation.

Canadian Associations Hold Joint Meeting in Quebec.—The Canadian Public Health Association held its fifth annual meeting in Quebec, Wednesday and Thursday, September 13th and 14th, conjointly with the Canadian Association for the Prevention of Tuberculosis, which held its fifteenth annual meeting on September 12th and 13th, and the Services sanitaires de la Province de Québec, which held its sixth annual meeting on September 12th, 13th, and 14th. The general sessions of each association were held in the City Hall and the evening sessions for September 12th and 13th were held in Promotion Hall, Laval University. At a public meeting of the three organizations, held on Thursday evening, September 14th, in City Hall, Sir James A. Grant, of Ottawa, delivered an address on Carriers of Disease; Ex-Controller McCarthy, of Toronto, spoke on the Economic Value of Preventive Medicine, and Dr. J. A. Beaudoin, médecin municipal, Lachine, P. Q., addressed the conference on *l'Importance de l'hygiène dans l'administration municipale.* After the meeting a smoker was held in the Château Frontenac. Friday, September 15th, was devoted to an excursion to the Saguenay River, calling at Grosse Isle Quarantine Station. The local committee of arrangements was composed of the following members: Honorary president, Dr. A. Simard; president, Dr. J. D. Pagé; joint secretaries, Dr. Emile Nadeau and Dr. Edgar Couillard; treasurer, Dr. P. H. Bédard.

Examination for Medical Intern, St. Elizabeth's Hospital.—The United States Civil Service Commission will hold an examination on October 4th, open to both men and women, to secure a list of eligible persons for the position of medical intern, St. Elizabeth's Hospital, formerly the Government Hospital for the Insane, Washington, D. C. The positions are tenable for one year and pay $75 a month and maintenance. Applicants must be twenty years of age or over and unmarried. For further information regarding the examination, address the United States Civil Service Commission, Washington, D. C.

Joint Meeting of Connecticut Medical Societies.—The 152d semiannual meeting of the Litchfield County Medical Association will be held in conjunction with the ninth semiannual meeting of the Connecticut State Medical Society, on Tuesday, October 3d, at the Charlotte Hungerford Hospital, Torrington. Dr. D. D. Reidy, of Winsted, will deliver the address of welcome, which will be followed by an address by Dr. Samuel M. Garlick, of Bridgeport, president of the State society. Dr. Joseph I. Linde, of New Haven, will read a paper on Infantile Paralysis, and Dr. Herbert K. Thoms, of New Haven, one on Post Partum Hemorrhage. Guests will have an opportunity to inspect the new hospital before the meeting is called to order.

Child Labor Bill No Fake.—The National Child Labor Committee has issued a protest against current statements to the effect that the recently passed Federal child labor law is a fraud and a joker. "We hope no one will be misled by these rumors," says Owen R. Lovejoy, general secretary of the committee. "The law is as airtight as a law can be. The thirty day clause which has been attacked as a 'joker' does not relate to shipment in interstate commerce but to removal from the factory, and was intended, chiefly, to prevent evasion of the law by the storage of child made goods in a warehouse. The Federal child labor law was framed by the best constitutional lawyers in the country; it was passed by a Congress that had given it close attention; and we of the National Child Labor Committee believe that, whether the next president be Mr. Wilson or Mr. Hughes, the child labor law can and will be enforced in accordance with the will of the American people."

Municipal Civil Service Examinations.—The Municipal Civil Service Commission of New York will hold examinations on October 6th to fill the positions of surgeon to the Police Department and medical officer to the Fire Department. Candidates must be between twenty-six and forty years of age, must be residents of New York State, and have had five years' experience. These positions carry a salary of $3,500 a year and present unusual opportunities for exceptional and valuable experience.

It is interesting to note that the duties of medical officers in the two big departments formerly consisted of attending and relieving the sick or injured, whether members of the department or not, in a manner similar to that of the present ambulance doctors. As time went on, accident cases increased so rapidly with the growth of the city that it was impossible to provide sufficient medical men to meet the demand without impairing the main function of the department to protect life and property. As a result, the present ambulance service was inaugurated and the Police Department was entirely relieved of the unfair burden.

At the present time the duties of the twenty surgeons of the Police Department and the ten medical officers of the Fire Department are very similar, except that the latter maintains one active clinic where the members of the department are supplied with medicine free. The Police Department contemplate inaugurating a clinic modeled after the one of the Fire Department. The physicians' duties consist of examining all successful candidates for the service prior to their final acceptance, caring for members during sickness and disability, and recommending for retirement those unfit or beyond the age limit for duty.

Added to the prestige of the rank of Battalion Chief in the Fire Department and of Inspector in the Police Department, medical men are eligible for retirement at half pay after twenty years of service.

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Professor of Pharmacology and Therapeutics, University of Southern California.

Thirty-seventh Communication.

TUBERCULOSIS (CONTINUED).

Locality in the treatment of tuberculosis is a minor problem, except in relatively few cases. Not infrequently one patient responds to treatment more readily in a dry climate, while another shows more rapid improvement in a humid atmosphere; but the primal considerations are that the patient shall be under strict disciplinary control, that the nutrition shall be adequate, that the atmosphere shall be reasonably free from debilitating contaminations, and that the environment shall be conducive to both physical and mental repose.

Inasmuch as several recent textbooks on the practice of medicine recommend sundry drugs in the treatment of tuberculosis, it becomes incumbent on the pharmacologist to examine these recommendations; but it is desirable that a distinction be made between drugs which have some favor as alleged cures and those which are frankly acknowledged as merely palliative in the later stages of apparently hopeless cases.

The use of tuberculin, in minutely ascending doses, has been given extended trial in some of the Adirondack resorts, the object being to establish an antitoxic immunity; but the results, while gratifying in many instances, are not yet of such extent and character as to gain general acceptation for this method of treatment.

Creosote and codliver oil were in much repute ten to twenty years ago, and are still lauded in a recent textbook, yet it is doubtful whether any beneficial result in the treatment of tuberculosis may be attributed directly to either of these substances. Creosote has been administered orally, rectally, hypodermically, and intratracheally, to the utter loathing of the long suffering patient; yet under this treatment no one has computed the ratio of deaths to recoveries, nor established the relation of creosote to either.

Concerning the oil a recent textbook says: "Codliver oil is another special remedy of great value"; yet there is not one shred of reliable evidence to prove that codliver oil is of any utility in the treatment of tuberculosis. Moreover, its nauseating smell, its heavy disgusting feel on the tongue, and its relative difficulty of emulsification in the duodenum, all make it prejudicial to the accelerated nutritive anabolism fundamental to the present method of treatment. Codliver oil should be thrust into the same discard with creosote and the hypophosphites.

Does anemia exist, the carbonate and the citrate of iron may be justifiably recommended as adjuvants; arsenic is sometimes helpful for its stimulant effect on the hematopoietic tissues. A syphilitic taint may demand the addition of mercury and the iodides, but any amelioration thus obtained does not indicate, as was once assumed, that mercury is a valuable drug in tuberculosis. Possibly some enterprising experimenter may yet find a synthetic specific in the treatment of tuberculosis as salvarsan sometimes is in chronic syphilis, but such a compound has not yet appeared; in fact we possess no drug at present that is of positive curative utility for this dread disease.

The distressing cough of the later stages is best inhibited by some agent which checks reflexes, like codeine; but as the cough is usually Nature's measure for removing accumulated secretions, its complete inhibition is undesirable. The fever requires no specific treatment except when unduly high. Fever in tuberculosis is an important indicator which registers the degree of success of general treatment; antipyretics temporarily mask the gauge, giving no adequate compensation in return. The night sweats are best treated with atropine.

In all treatment of tuberculosis the important thing to bear in mind is the urgency of early diagnosis, followed by prompt and energetic attention to hygienic measures as a mode of treatment.

Intensive Treatment of Syphilis. — Loyd Thompson (*Journal A. M. A.*, Sept. 2, 1916) states that the earlier in the disease one begins treatment the better the chances of cure, but the diagnosis should always be made certain by finding the spirochetes, or by obtaining a positive Wassermann reaction. Treatment must be pushed to the limit of tolerance and continued with intermissions until there is clinical cure and a persistently negative Wassermann. The initial dose of salvarsan should be 0.4 gram dissolved in forty mils of freshly distilled water and given intravenously. Beginning the following day intramuscular or intravenous injections of mercury should be started. The benzoate of mercury is the best preparation for intramuscular injection and should be prepared by dissolving 2.5 grams of chemically pure sodium chloride in fifty mils of distilled water in a graduated flask. Then two grams of benzoate of mercury are added and dissolved by shaking. Distilled water is added to make 100 mils, and the initial dose is 0.5 mil, containing 0.01 gram of the mercurial This dose is rapidly raised to one mil, or 0.02 gram. For intravenous injection the requisite dose of mercuric chloride in a two per cent. solution is dropped into a twenty mil glass syringe containing ten mils of normal saline. The whole is shaken, the air expelled, the needle inserted into a vein and blood drawn in to fill the syringe. The contents are then injected slowly. All cases of cerebrospinal syphilis require intradural treatment, which is best carried out as follows: Salvarsanized serum is prepared freshly by adding 0.1 mil of a

fresh solution of salvarsan (0.25 mgm.) to one mil of fresh serum, incubating at 37.5° C. for three quarters of an hour and inactivating at 55° C. for thirty minutes. Under novocaine anesthesia the needle is inserted in the lumbar region connected with twenty-five cm. of rubber tubing to the barrel of a twenty mil glass syringe, which is then lowered until about fifteen mils of spinal fluid collect in it. Then one or two mils of a five per cent. novocaine solution are added, and the whole is allowed to run back into the dural space. After three minutes' spinal fluid is again collected in the syringe barrel and the salvarsanized serum added and injected as before. Mercurialized serum may be given in the same way. Potassium iodide must be given in addition to salvarsan and mercury in cases with gummas or arteritis.

Ringworm of Hands and Feet.—Oliver S. Ormsby and James Herbert Mitchell (*Jour. A. M. A.*, Sept. 2, 1916) show that the involvement of the glabrous skin surfaces of the hands and feet by ringworm is far more common than is usually believed. Since the lesions produced in these regions resemble closely several common dermatoses, the diagnosis must rest on the discovery of the parasite. Treatment is successful, but should differ according to the lesions. In severe purulent and eczematoid forms, preliminary use of a soothing application of naphtalin with zinc oxide and starch should be prescribed, followed by application of a five per cent. solution of chrysarobin in a chloroform solution of gutta percha. Five daily applications of the latter are usually sufficient. If not, the treatment may be repeated after an interval of three days. In other forms chrysarobin alone may be used, or more prompt results may be secured from an ointment of the following composition:

℞ Acidi salicylici, ...2.0;
Acidi benzoici, ...4.0;
M. Unguenti simplicis, ...30.0.

This may be used daily for several weeks, if necessary, without causing irritation.

Treatment of Gonorrheal Conjunctivitis.—J. H. Claiborne (*Virginia Medical Semi-Monthly*, July 21, 1916), in gonococcal conjunctivitis of the newborn, advises the use of two per cent. silver nitrate solution every other day, the eyes being meanwhile kept clean with boric acid solution. If the lids are much swollen, ice should be applied from time to time. Manipulation of the lids should be avoided as much as possible; slight external pressure on the lids with the finger tips should alone be used to evert them for the instillation. The silver nitrate should be discontinued when the secretion begins to lessen, or sooner if it causes undue irritation. In cases seen only when there is already great thickening of the lids, with a membrane and a brawny condition of the mucosa, thirty per cent. argyrol solution should be substituted for silver nitrate. Where corneal ulcer appears a one per cent. solution of atropine sulphate should be used, and one should cease trying to inspect the cornea. After the discharge has stopped and the lids are improved, occasional use of silver nitrate on the succulent lids will promote recovery. In gonococcal conjunctivitis of the adult, Claiborne succeeded in two consecutive cases in which the disease had been under way from twelve to forty-eight hours in aborting the process with silver nitrate. The sound eye was sealed hermetically, the patient put to bed, the conjunctival sac washed out, and six or eight drops of two per cent. silver nitrate solution instilled and allowed to remain twenty to thirty seconds. This was then washed out with one in 3000 mercury bichloride solution, and ice applications given day and night as often as required to keep the lids chilled. Every hour the nurse, gently lifting the upper lid with the thumb, wiped away any secretion formed and instilled boric acid solution. The lids swelled somewhat and slight chemosis developed, but in two days the disease was under control. In each of these two cases the eye had originally shown at the inner canthus a bead of yellowish pus containing numerous gonococci. Soon after the infection in the first eye had been controlled the second eye in each case became involved, but this was soon subdued by like treatment, and in two weeks neither case showed any trace of the disease, save a slight redness of the lids.

Treatment of Nerve Injuries.—S. Loewenthal (*Berlin. klin. Woch.*, February 28, 1916) considers that the prime indication for treatment, other than restoration of function, is relief of pain. This is often difficult, but among the most satisfactory measures are: Judicious use of small doses of morphine; cold, moist applications or baths; in some cases, moist, hot applications; antineuralgics, such as pyramidon in single doses of 0.4 to 0.6 gram; and the local inunction of a two per cent. veratrine salve, for which the following is an excellent formula:

℞ Veratrinæ, ...1.0;
Adipis vel vasogen, ...ad. 50.0.
M. External use only.

Colchicum and cannabis indica have proved worthless in the control of this form of pain. If the lesion is not recovered from after sufficient time, during which expectant treatment has been employed, then operative treatment of the lesion causing the disturbance should be considered.

Treatment of Condylomata acuminata.—David Watson (*Medical Standard*, August, 1916) finds that the treatment for venereal warts which is most simple, effective, and free from objection is application of lactic acid. The mode of employment depends on the conditions. In the male circumcision is performed first when necessary, then pedunculated warts may be removed with scissors, and pure lactic acid is applied to the base after the bleeding has been controlled. Other growths are treated with a continuous one per cent. wet dressing, or with the occasional application of a strong solution. In the female, when there are several large masses, each portion is isolated and kept surrounded by strips of lint wet with a one half to a one per cent. solution. The base of these growths may also be touched with the pure acid at intervals of a few days. Smaller growths are painted with the undiluted acid or a strong solution, and when there is a large field of minute growths the wet dressing is employed. The dressings are changed

in accordance with the discharge, and at each change the parts are thoroughly bathed with an antiseptic; in the case of females a sitz bath is used. The largest masses wither and drop off, small growths are inhibited, and cure results without formation of cicatrices and without pain. The only disadvantage the writer has encountered in the use of lactic acid is the occasional occurrence of a general erythema when the treatment is pushed too energetically. This erythema is of trifling significance and subsides quickly on the temporary withdrawal of the acid and the substitution of a zinc and calomel dusting powder or ointment, but when large areas are involved it may be necessary to intermit the treatment for two days each week, and to protect the surrounding healthy tissues with petrolatum in order to discourage excessive absorption of the acid. As soon as the seats of gonorrheal infection can be reached appropriate treatment is instituted.

Vaccine Treatment of Whooping Cough.—Charles James Bloom (*New Orleans Medical and Surgical Journal*, September, 1916) states that the treatment of pertussis by vaccine is most efficient provided the procedure followed is correct. Give a large initial dose, not less than 120,000,000, increase 60,000,000 for each succeeding dose, and give the maximum quantity every other day until one of the marked symptoms shows an appreciable improvement. Continue every three or four days until the patient is cured. Vaccine produces no reaction, it reduces the duration of an attack to an average of twenty-eight days, the loss of weight is minimum, the intensity and number of coughing spells become less after three injections have been given, vomiting ceases after six injections, sleep is not disturbed after from five to twelve days, and no complications were observed by the writer in thirteen cases after observation ranging from eight to twelve months.

Sodium Citrate and Sodium Chloride for the Prevention of Interperitoneal Postoperative Adhesions.—J. Wesley Bovee (*Surgery, Gynecology, and Obstetrics*, September, 1916) says that acting upon the theory that "before a fibrous exudate can form in the peritoneal cavity, with its resultant plastic agglutination, there must be the liberation of that hypothetical ferment, thrombokinase, its activation of prothrombin in the presence of calcium and the production of thrombin," Saxon Pope experimented on sixty rabbits and published his work in January, 1914. These experiments were made with many different materials and he concluded that a solution of a two per cent. sodium citrate in a two per cent. solution of sodium chloride was the best remedy. His faith in his conclusions is proved by his reporting in February, 1916, the results of the employment of this hypertonic solution in 400 abdominal operations in the University of California Hospital. Walker and Ferguson during 104 operations on sixty-three rabbits found three per cent. of the citrate in one per cent. of sodium chloride solution was the most satisfactory, giving complete success in 70.5 per cent. and in 88.2 per cent. partial success. In the presence of sepsis or deep or wide destruction of tissue it is not stated that these hypertonic solutions can be regarded as infallible, but even here they are of use. In Bovee's personal experience with the three per cent. solution of the citrate in quantities of 200 to 300 c. c. shock has been noted. Among the questions that arise in our minds are: 1. If it gives absolute success in 70.5 per cent. of cases of mild peritoneal traumatism, can its use be extended successfully in more severe peritoneal injuries such as separated adhesions? 2. How long must it be in contact with the area to be of the highest efficiency? 3. What is the duration of its activity? 4. Can it be used efficiently in gauze covering large areas of peritoneal denudations, and brought out through the abdominal wall? If these questions are answered later satisfactorily, then we shall have positively mastered the much dreaded and dangerous complication of peritoneal adhesions.

Treatment of Sydenham's Chorea.—Augusto Natali (*American Medicine*, August, 1916) concludes that intraspinal injections of magnesium sulphate in the proportions and doses indicated by Marinesco give good results. This is particularly true of cases of chorea minor, where soon after the first injection improvement is usually noticed. In some cases improvement is progressive up to the time of recovery. Others need a second or a third injection before improvement sets in or recovery takes place. Recurrences are rare. A short treatment with arsenic following the injections is of value. The method is not to be used in all cases of chorea, but should be restricted to two classes of cases: a, Those in which other treatment has not given good results, and, b, those in which the choreic movements are pronounced to the point of interfering with the patient's rest.

Administration of Diphtheria Antitoxin. Safety First.—Louis Weiss (*Medical Review of Reviews*, September, 1916) urges that this is an important procedure, to be prepared for and carried out with infinite care. The history should be ascertained, and the present condition of the patient carefully noted, with especial attention to the heart. The patient should always be in the recumbent position, no matter what the age, in order that the work of the heart may be as light as possible. Cleanse the skin of the part selected with ordinary hand soap, or tincture of green soap, or lysol in solution, and paint with tincture of iodine. Cleanse your own hands. The antitoxin outfit comes to you sterilized. Pinch up the skin and introduce the needle through the iodine stained area. With the syringe in one hand ready for action feel the pulse with the fingers of the other hand, or with the stethoscope over the heart. Inject drop by drop, slowly and carefully. If the heart continues as before or improves, continue the injection until finished, but if the heart shows a tendency from normal, or grows worse in any way, remove the needle at once. The pulse shows the first sign of danger, which is detected easily. If the pulse is overlooked and the injection continued, other symptoms may follow: A temporary stoppage of respiration, a blank stare, an anemic, shrunken face, beads of cold perspiration on the forehead, dropping of the arms and head to one side, and collapse. Such an experience does not occur if the slow, careful, watchful, drop by drop method is followed with the patient in the recumbent position.

Pituitrin in Labor.—Frank Perry (*American Medicine,* August, 1916) records twenty-three cases in which pituitrin was used. The dose employed was one c. c. and in several cases it had to be repeated. A summary of the cases shows that labor pains were induced in from three to five minutes. They were intermittent at first, but became regular in about fifteen minutes. Delivery of the child was hastened and expulsion of the placenta was accelerated. An agreeable aftereffect of the remedy is its favorable influence on the evacuation of the bladder. It should not be used in anatomical obstruction of the birth canal, nephritis with high blood pressure, or exophthalmic goitre. Where secondary hemorrhage is anticipated, it may be given late in the secondary stage. He advises against the early use of pituitrin. Before its administration, the cervix should first be well dilated and rigidity should be overcome.

Chancroids.—Goubeau (*Jour. A. M. A.,* September 9, 1916) uses cotton swabs soaked in ether, each ulcer being cleaned and freed fom all traces of pus. The surface is then swabbed with a solution of the following composition:

℞ Sodii arsenatis, ...1.0;
Alcohol, ...50.0.
M. et fiat solutio. S. External use only.

The alcohol is allowed to evaporate in a current of air, leaving a thin film of sodium arsenate covering the surface and lining all of the minute crevices. The swabbing is repeated once, and a dry gauze dressing is applied after the alcohol has again evaporated. This treatment is carried out daily for three to four days, when the chancroid will have become a small, healthy wound which should be sponged with ether and dusted with iodoform once a day. Healing is usually complete in ten days. For buboes one may aspirate the pus and inject one mil of a one per cent. aqueous solution of arsenate of soda every two days if necessary. The same treatment should be used even before pus has formed.

Goitre.—Harry G. Sloan (*Cleveland Med. Jour.,* July, 1916) states that since thyroid trouble is prevalent in certain localities in which there seems to be a deficiency of iodine in the food, such as the Great Lakes region, it is well to prescribe small amounts of iodine for children as they approach and go through puberty, and a similar plan is advisable in pregnant women. For this purpose it is enough to give 0.3 mil of the syrup of the iodide of iron after meals for one month out of every three. This preparation also supplies a small amount of iron which is beneficial. In any case of goitre one should make a careful physical examination to locate any foci of infection. If found, these should be eradicated before any form of treatment may be expected to give fully satisfactory results. Such examination should include the teeth, the nasopharynx and the sinuses emptying into it, the uterus, prostate, and similar regions likely to be overlooked. The condition of the alimentary canal should also be investigated and if there is any reason to suspect toxic absorption from stasis or fermentation, measures should be taken to secure proper regular evacuations; it is well in addition to prescribe capsules containing 0.3 gram of thymol, one to be taken after each meal. The regular use of buttermilk and the administration of small doses of iodine should be combined with these measures in Graves's disease, but we must be on the watch to control the dose of iodine, so as not to produce an increase in the symptoms. Usually after four to six weeks of regular administration of iodine, the gland will begin to diminish in size and become firmer. The patient must be placed at complete rest in bed for a month or more, if Graves's disease is present, and if at the end of that time there has been no decided improvement, it is then appropriate to consider the need for resort to some one of the accepted surgical modes of attack.

Complement Fixation in Tuberculosis.—H. J. Corper (*Journal of Infectious Diseases,* September, 1916) points out the necessity of being able to determine the presence or absence of tuberculosis at a time when tubercle bacilli are not present in the sputum. At present the complement fixation test is being employed and the technic is being improved until Doctor Corper thinks that it may become as valuable a reaction as the Wassermann in syphilis. The results of his experiments, however, hardly seem to justify his optimism. He found that the test was positive in only about thirty per cent. of all the clinically definite cases of tuberculosis, both active and inactive. Its chief claim to value seems to be that a positive reaction is practically final.

Seborrheic Eczema.—A. Winkelried Williams (*Medical Standard,* September, 1916) includes under this term a number of skin diseases commonly supposed to be distinct, but which he thinks are divided only by endless synonyms. Perhaps the ordinary name by which it is known is dandruff, but he defines it as a type of the parasitic forms of eczema. Acne and impacted cerumen of the external auditory meatus are mentioned as complications, or possibly varieties. He states that local treatment will cure seborrheic eczema, and that scalp treatment is imperative, as otherwise recurrences and exacerbations are inevitable except in a small percentage of the rarer cases of ascending eczemas. In case of infants cleanse the scalp with boric starch dressings, one teaspoonful of boric acid and four tablespoonfuls of starch mixed with a little cold water over which a pint of boiling water is poured so as to form a jelly to be spread three fourths of an inch thick on linen or calico, allowed to cool, covered with muslin, and applied. The scalp should be covered with impervious wool or jaconet, and the dressing should remain on a few hours. After its removal if the crusts are not wiped off easily the dressing should be reapplied. After removal of the crusts a mild antiseptic ointment should be applied, such as boric acid in lanolin and olive oil. If the infant has little or no hair, Ihle's paste may be used. If there is pustulation we may use:

℞ Hydrargyri ammonii chlorinati, ...gr. x;
Petrolati, ...5j.
M. ft. mist.

or, if in addition to the pustulation there is much liquid exudation, he recommends eight grains of the mercurial salt in two drams each of zinc oxide, starch, lanolin, and olive oil.

Older children and adults should have the scalp cleansed with this wash:

℞ Ammonii carbonati, ...3ij';
Sodii biboratis, ...3iv;
Aquæ, ...ad 3xij;
Solve, deinde adde:
Glycerini, ...3vii;
Spiritus vini rect., ...3vij.
M. ft. mist.

which should be rubbed in freely and allowed to soak into the scalp for ten to twenty minutes, or until the scalp tingles. Then the head should be washed with soap and hot water and dried well. Medication should be applied by means of an ointment, a pomade, or a lotion. When there is a large quantity of scaling, ointments usually are the best to begin with.

℞ Sulphuris præcipitati, ...3ss ad 3j.
Acidi tannici, ...gr. xx ad xxx;
Adipis benzoati, ...3j.
M. ft. unguentum.

the stronger to be used when there is no distinct redness of the skin, or Unna's pomade:

℞ Resorcini, ...gr. xiii;
Sulphuris præcipitati, ...gr. xxv;
Olei amygdalis dulcis, ...3vii;
Olei theobromæ, ...3iv.
M. ft. unguentum.

The hair should be parted at two inch intervals and a small quantity of the ointment or pomade rubbed along the parting lines on the skin, getting as little as possible on the hair shafts.

A good lotion is:

℞ Resorcini, ...gr. lxx ad c;
Olei ricini, ...3iii ad 3v;
Spiritus vini recti (80 per cent.), ...ad 3iii;
Aquæ cologniensis, ...3ss.
M. ft. lotio.

the stronger to be used in chronic cases, the weaker in the more acute.

An essential detail is the prior cleansing and disinfection of brushes and combs and twice weekly during treatment. They should be soaked for ten minutes in hot soda, and then rinsed in several lots of cold water. Pillow cases, hats, and wigs are similarly infected, but are less dangerous.

The writer then passes to the treatment of the skin where it is not covered by hair, dealing exclusively with adults and older children, not infants. The varied types require modifications. First, cases with dry or slightly greasy scaling from slightly raised or nearly plane, somewhat reddened or yellow surfaces. Wash with superfatted soap, dry thoroughly, and apply one of these ointments:

℞ Sulphuris præcipitati, ...3ss;
Acidi tannici, ...gr. xx;
Adipis benzoati, ...3i ad x.
M. ft. unguentum.

℞ Liquoris carbonis detergentis, ...3ss;
Hydrarg. am. chlor., ...gr. x;
Petrolati, ...3j.
M. ft. unguentum.

℞ Resorcini, ...3ss;
Sulphuris præcipitati, ...3ss;
Adipis lanæ, ...3vi;
Olei olivæ, ...3ij.
M. ft. unguentum.

Second, cases without very acute signs, but considerable scaling, resembling chronic psoriasis: Patient should soak in hot bath for half an hour. It is better to add to each thirty gallons of water a quarter of a pound each of tannic acid or borax. The scales should be scrubbed off, using soft soap if necessary. After drying, rub the patches well with a test ointment, such as

℞ Acidi salicylici, ...gr. xxx;
Liq. carbonis detergentis, ...3ss;
Petrolati, ...3j.
M. ft. unguentum.

and if the skin bears this well use the next day:

℞ Chrysarobin, ...3 to 6 parts;
Ichthyol, ...4 to 6 parts;
Acid salicylic, ...2.5 parts;
Benzoated lard, ...to 100 parts.

The weaker should be used first, the stronger a few days later if a good reaction is not obtained. It should be applied twice a day, at first being merely smeared over the patches, later rubbed in with a flannel if the skin bears it. Chrysarobin should never be used on the head, as it may excite a serious inflammation of the eyes. After four days' use of this ointment, or less if it causes an acute inflammatory reaction, the patient should take another bath. If the areas have lost all thickening and are surrounded by erythema, an ointment is substituted such as

℞ Sulphuris præcipitati, }
Acidi tannici, ... } .....āā gr. xx;
Adipis benzoati, ...3j.

℞ Hydrargyri ammonii chlorinati, ...gr. v;
Liquoris carbonis detergentis, ...3ss;
Petrolati, ...3j.
M. ft. unguentum.

When no distinct reaction has been caused, another four days' treatment with an increased strength of chrysarobin should be instituted.

A third type is acute cases complicated with vesication. Keep the patient quiet and soothe the skin with dusting powders. Then apply a mild paste until the skin becomes dry, and administer the treatment for the first type.

The fourth type resembles pityriasis rubra and should be treated with the tannic acid and borax bath, inunction with unguentum glycerini plumbi subacetici, and when the case has been reduced to localized areas, like the first type.

For treatment of the external auditory meatus, it is recommended that after the cerumen and scales have been washed out and the meatus dried, the irritated skin should be carefully swabbed with a solution of silver nitrate in spirits of nitrous ether, gr. xii to 3j, after which an ointment of twenty or thirty grains of tannic acid to the ounce may be applied. Another application said to be recommended by G. Elliot is one part of resorcin in ninety-nine parts of benzoinal.

The umbilicus may be cleaned with a solution of borax, then painted with the foregoing solution of silver nitrate, and an ointment applied of

℞ Acidi salicylici, ...gr. xv;
Sulphuris præcipitatis, ...gr. xx;
Petrolati, ...3j.
M. ft. unguentum.

rubbed in and then applied on lint fastened by a pad and bandage.

For seborrheic eczema in the axilla, use ichthyol, sulphur, or tannic acid ointment spread on strips of lint made to fit and kept in place by a lady's axillary dress protector with a pad between the wings secured by a bandage.

Miscellany from Home and Foreign Journals

Fever in the Puerperium and Puerperal Fever.—F. Villanueva (*Revista de Medicina y Cirugia Practicas,* August 14, 1916) states that every woman during the puerperium is exposed to various morbid processes, which must not be looked upon as caused by puerperal infection. Proper treatment of puerperal infection depends largely upon proper diagnosis, both clinical and bacteriological. Care should be taken that a given suspected infection is real before beginning treatment, and intercurrent or accidental disease requires quite as careful treatment. Errors in diagnosis are almost always produced by a mental predilection that all puerperal fever should be considered as caused by puerperal infection.

Babinski's Sign.—M. Astwazaturof (*Brit. Med. Jour.,* Aug. 12, 1916) states that various unsatisfactory explanations have been offered in connection with the mechanism of this important diagnostic sign, but that no one has done much more than restate the fact without elucidation. The author, however, attempts an explanation on the basis of ontogeny. The sign is normally present in infants before walking begins, and in certain primates a transitional stage in the development of the great toe from the thumb is present. With this development of the toe not all of the original reflexes are lost, but that of extension is held to be suppressed by cortical inhibition, and is normally replaced in man by a cortical reflex which causes a simultaneous flexion of all five toes. This reflex passes by way of the pyramidal tracts, and hence lesion of these tracts gives rise to the older, suppressed extensor reflex of the great toe by virtue of a release of the cortical inhibition. The Babinski reflex is a purely segmental spinal phenomenon. The same explanation holds for these similar reflexes observed by Oppenheim, Gordon and others.

An Anomaly of the Widal Reaction.—A. F. S. Sladden (*Lancet,* Aug. 12, 1916) remarks that when a macroscopic method is employed, a "zone phenomenon" is occasionally observed in which there is no agglutination with the lower dilutions, while agglutination occurs with the higher ones. Using Dreyer's method, the author studied this phenomenon as it occurred with B. typhosus and B. paratyphosus A and B. He observed it thirty-five times in a series of 116 different serums. The average range of its occurrence was found to be: for B. typhosus in dilutions up to one in fifty of serum; B. paratyphosus A up to one in twelve; and B. paratyphosus B up to one in eighty. It was found that the addition of another serum to the one being tested would increase the zone of inhibition of the former. The use of salt solution as a diluent had a similar effect, while distilled water diminished the zone and rendered the reaction more delicate. Where there was a marked zone of inhibition in a serum of feeble agglutinating power, the latter might be altogether missed if only a short range of dilutions was used. The extent of the zone, when present, increased as the infection progressed. Zone phenomena were present for all three organisms, but in varying degrees.

Obstetrical Paralysis—An Orthopedic Problem.—James Warren Sever (*American Journal of Orthopedic Surgery,* August, 1916) finds, from a study of 471 reported cases, that the paralysis is always due to force during a difficult labor; that it occurs more frequently on the right side and in cases with head presentation; that the upper arm type is more frequent; the prognosis in this type is more favorable; it may be associated with fracture of the clavicle, but does not result from a fracture of the humerus or a dislocation of the shoulder. He believes that the condition is due to injury of the cervical roots of the brachial plexus. He performs a modified Fairbanks' operation in which he divides the pectoralis major and the tendon of the subscapularis and, if necessary, the coracobrachialis and the short head of the biceps, and then applies a cast with the arm held in elevation, abduction and outward rotation and the hand in supination.

Trismus during Serum Sickness.—R. F. Bolt (*Brit. Med. Jour.,* Aug. 12, 1916) reports that while operating on an empyema a medical officer pricked his finger, which promptly became septic. The finger was incised and fifteen mils of antistreptococcic serum were administered. Eleven days later an urticarial rash developed; the next day there was fever and a severe headache; and on the following day—thirteen days after the dose of serum—the victim had pain in the neck, back and extremities, stiffness of various muscles and trismus. Treatment with the salicylate of soda, chloral and morphine reduced the symptoms and the patient recovered after about five days of trismus. The trismus and muscular symptoms were thought to be due to serum sickness, although tetanus could not be excluded absolutely. The patient from whom the original infection was derived made an uneventful recovery without symptoms of tetanus.

Precancerous Dermatoses.—W. J. Heimann (*Journal of Cancer Research,* July, 1916) states that carcinoma so frequently develops from certain dermatoses as to exclude mere coincidence, yet these dermatoses cannot properly be called precancerous lesions. It is very evident that many carcinomas are not preceded by such changes, and that every so called "precancerous dermatosis" does not invariably lead to cancer. Heimann maintains that the precancerous stage is unrecognizable, both clinically and microscopically. It was evident that at some stage in the evolution of the tumor there was a point separating the noncancerous from the cancerous, but as yet there is no way by which this may be recognized. There is, however, a group of lesions which frequently terminate as epitheliomas, yet neither their gross nor their minute appearance is that of cancer, nor do they possess peculiarities so separating them from other lesions as to make it possible arbitrarily to consider them the forerunners of cancer. It may be that individual experience will justify the impression that such lesions are capable of leading to cancer, but this is improbable.

Specificity of Wassermann Reaction.—Rudolph Bahman (*Surgery, Gynecology and Obstetrics,* September, 1916) concludes thus regarding the specificity of the Wassermann reaction: Theoretically, the Wassermann reaction is not specific, but practically it is highly specific. A strong positive reaction with proper controls and accurately titrated reagents is conclusive evidence of syphilis. The diagnosis of syphilis cannot be made upon a weakly positive reaction without some clinical evidence of the disease. A negative reaction does not exclude a syphilitic infection. Malignant diseases do not give positive reactions.

Cessation of Tachycardia on Outbreak of Spontaneous Perspiration.—Thomas Oliver (*Lancet,* August 5, 1916) states that a young man, twenty-eight years of age, suffered a severe attack of paroxysmal tachycardia accompanied with cyanosis, pallor and recurrent vomiting. Remedies failed to relieve the tachycardia, but after several hours profuse sweating began spontaneously and brought prompt relief from all symptoms, including the tachycardia. The patient had experienced similar attacks and relief had always come in the same way. No explanation of the phenomenon could be given.

Unexpected Results of Testicle Grafting.—Robert T. Morris (*Jour. A. M. A.,* Sept. 2, 1916) grafted three small fragments of testicle excised from a healthy man fifty-four years of age, into a man twenty-seven years of age, fourteen years after apparent total atrophy of his testicles from mumps. All three grafts underwent absorption, but the remnant of the man's right testicle near which one graft had been made, began to enlarge, and a testicle about one third normal size developed and was still growing when seen a year after operation. Along with the growth of the testicle there were developed some of the normal sexual characteristics which had previously been wanting, including the power of erection, enlargement in the size of the penis, and a normal libido.

Continuous Morning Headache in Arterial Hypertension.—Louis Rénon (*Paris médical,* July 1, 1916) finds this special form of headache more frequent in men than in women. It is seen exclusively in subjects forty-five to sixty years of age, chiefly around the fiftieth year, and is associated with arteriorenal sclerosis, whether due to interstitial nephritis following scarlet fever in childhood, to neglected syphilis, tobacco intoxication, or excessive eating of meats. A sedentary occupation, mental overwork, and worry are also factors. The hypertension is characterized by a high diastolic pressure—140 to 170 mm. with the Pachon, somewhat lower with other instruments—with the systolic pressure at 240 mm. (Pachon) or higher. The headache may be diffuse or be limited to the right and left frontal or parietal region, or both these areas; it is seldom occipital. It awakens the patient at 5 to 7 a. m., grows worse at 9 or 10 a. m. and tends to disappear about noon or an hour after lunch. The tortured patient, however, seldom lets it run its course, usually relieving it for a time with divers analgesic tablets, often with chronic drug intoxication as an ultimate result. The heart in these patients is large, the left ventricle hypertrophied, the urinary output much increased, with slight albuminuria. In some less pronounced cases, the headache is dull on arising, but becomes acute and unbearable upon the least physical or mental exertion—walking, going upstairs, or writing and thinking (the so called "painful thought" of Josué). These forms of headache, though remitting under treatment, are rarely cured, and render the prognosis of the high pressure cases in which they are found much worse, death usually following some overexertion or dietetic error and being due usually to apoplexy, less often to acute pulmonary edema, heart failure, angina pectoris, or uremia. The headache is of mechanical rather than toxic origin. Migraine attacks in arthritic patients are distinguished from it by their occurrence chiefly in younger patients, unilateral distribution, preceding vertigo, hereditary incidence, and coexisting disorders such as eczema, asthma, and lithiasis. The treatment of the headache consists, first of all, in breaking up the analgesic drug habit, forbidding the use of tobacco, and insisting upon complete rest, mental and physical. An exclusive milk diet—not exceeding two liters a day, with 2.5 grams of sodium citrate added to each—should be imposed for a week, and on two days in each of the second and third weeks. On the remaining days a vegetarian and fruit diet should be ordered. After the third week, fresh meat may be taken once daily, at the noon meal. A paper containing three grams of salt should be given to the patient each day, not to be exceeded during that day. If headache persists and the pressure fails to descend, thiosinamine and cratægus should be ordered for prolonged use. Iodides and antisyphilitic treatment may be of value.

Epidemic Pneumococcic Septicemia.—P. Carnot and De Kerdrel (*Paris médical,* July 8, 1916) call attention to certain epidemics of pneumonia recently noted among the Annamite and Senegalese native troops in the French service. The severe type of infection observed in these men combined the manifestations of ordinary lobar pneumonia with those of experimental pneumococcic septicemia in the rabbit or mouse. In some series of cases the blood of no less than one half the patients yielded a pure culture of pneumococci. Among the earlier cases, which arose in the winter time and while the men had insufficient shelter, the mortality was 100 per cent., the patients succumbing a few hours after admission; later, as the weather grew warmer, the mortality sank to fifty per cent., then lower, and finally the epidemic came to an end. Only nine of a series of eighteen cases showed frank lobar pneumonia, the others exhibiting lung congestion, acute edema, bronchopneumonia, hemorrhagic infarcts, etc. Concomitant pleurisy was noted in nine cases pericarditis caused death in many instances; peritonitis and otitis occurred four times, and marked splenic and hepatic enlargement was uniformly noted. The severity of the condition is ascribed to the marked susceptibility of the tropical troops suddenly exposed to rigorous climatic conditions. Treatment was of use only in the later mild cases. Gratifying results were obtained with subcutaneous injections of bile, local use of bile—notably in otitis—and especially by the use of pneumococcic vaccines in bile.

Physiology of the Phenols.—Dubin (*Jour. Biol. Chem.*, August, 1916) as well as others, believes that the urinary phenols arise from intestinal putrefaction, and are derived from the tyrosin portion of the protein molecule. Among the many conclusions drawn from his experiments he states that the phenols in the urine may be taken as an index of intestinal putrefaction.

New Spine Brace for the Rotation (Abbott) Treatment of Scoliosis.—H. Winnett Orr (*American Journal of Orthopedic Surgery*, August, 1916) describes a brace which consists of a posterior upright bar, fixed at the pelvis, with adjustable ribs on both sides for pressure. The ribs do not extend anteriorly, and hence no counterpressure at the chest can be obtained. The author states that rotation correction can be procured by its use and that it is easily fitted to any patient.

Typhoid Inoculation and Endemic Goitre.—M. A. Nicholson (*Lancet*, Aug. 12, 1916) through McCarrison's suggestion that endemic goitre is due to a waterborne intestinal organism and may be benefited by the use of vaccines of intestinal organisms, has been led to study the effect of typhoid inoculation on this disease. He made two series of observations on large groups of patients with equally large numbers of "controls." He was, however, unable to observe any effect from the vaccine on the size or prevalence of the goitre.

Treatment of Caries of the Spine by Bone Transplants—A Report of Twenty-three Cases.—Rutherford L. John (*American Journal of Orthopedic Surgery*, August, 1916) makes an unfavorable report of cases operated in. The author finds that half of the number were improved by bone transplanting, the remainder being reported as poor, indifferent, and resulting in death; that the incipient cases benefited most; that the danger of dissemination of the infection by operation may be often overlooked; and that the six deaths occurred in children of five years or less.

Effects of Retention in the Kidney of Media Employed in Pyelography.—William F. Braasch and Frank G. Mann (*American Journal of the Medical Sciences*, September, 1916) give the following conclusions derived from clinical and from experimental data. From clinical data: 1. The greatest danger in the use of silver preparations is their retention in actively secreting kidneys. 2. With multiple foci of necrosis the condition should be regarded as a septic nephritis and immediate nephrectomy is indicated. 3. Focal necrosis as the result of infection may follow the introduction of a ureteral catheter or of bland fluids into a pelvis with insufficient drainage. 4. Silver iodide suspensions are less harmful than the colloidal silver preparations. 5. Thorium nitrate in ten or fifteen per cent. solutions causes the least reaction, but casts a less distinct shadow. From experimental data: 1. Mild chemical irritants, as sodium chloride and boric acid, when injected and retained in the pelvis of the kidney, do not produce lesions of that organ. 2. The effect of methylene blue was practically negligible. 3. Stronger chemical irritants, as sodium citrate and twenty per cent. thorium nitrate, when tested in the same drastic manner, produce lesions of the kidney which seem to be directly due to the chemical injected, and not to any concomitant or subsequent infection. 4. Argyrol, collargol, and cargentos were about equally responsible for producing the most marked changes. It was often possible to find areas in which the metal could be distinguished. 5. The weaker solutions of colloidal silver did not appear to be less harmful than a more concentrated solution. 6. The silver iodide preparations produced less changes in the kidney than the other silver solutions. The one which is suspended in quince seed emulsion caused the least necrosis. 7. So far as determined, a fifteen per cent. thorium nitrate solution did not produce changes in the kidney, except possibly in one experiment. Care must be taken in its preparation that the solution is thoroughly neutralized.

A Case of Renal Calculi.—C. Thurston Holland (*Archives of Radiology and Electrotherapy*, August, 1916) cites the case of a woman forty-two years of age who complained of pain coming on in acute attacks throughout a period of ten years. The pain occurred on the right side and was associated with pain on micturition, and vomiting; the attacks were followed by the passage of large quantities of urine. Latterly the attacks had increased in severity. The right rectus was somewhat rigid, but the right kidney seemed palpable and was taken to be movable. The urine contained no pus and no albumin, but a few blood cells were reported. From radiographs the diagnosis of stone in the lower right ureter was suggested. Other tests were made which provided sufficient evidence for operation. In the abdomen high up in the kidney region on the right side, a tumor about the size of two oranges was found. It proved to be a dermoid cyst with a long pedicle, and the shadow which gave the impression of a ureteral stone was found to be caused by an immature tooth.

Effect of Potassium Iodide on the Luetin Reaction.—John A. Kolmer, Toitsu Matsunami, and Stuart Broadwell (*Jour. A. M. A.*, Sept. 2, 1916; note that Sherrick's observation that a positive luetin reaction occurred in ninety-nine per cent. of all persons, even if nonsyphilitic, if potassium iodide was administered shortly before, during, or immediately following the test, was confirmed in a series of careful investigations on normal subjects. Adequate "controls" were carried out, using the same material and the same subjects. The reaction was found to be positive in some persons as long as a month after the last dose of the iodide. Similar results were secured in guineapigs and rabbits. A marked reaction was also observed when agaragar was substituted for the luetin in iodized persons. Inflammatory reactions also developed at the site of previously negative luetin injections when potassium iodide was given subsequently. The dose of iodide required to cause positive reaction differed in the different subjects. These findings showed the necessity of care in interpreting the luetin reaction and the need of certainly excluding recent administration of iodide when the test is made.

Proceedings of National and Local Societies

THE AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Third Annual Meeting, Held at Washington, D. C., May 11 and 12, 1916.

The President, Dr. J. W. Jobling, of Nashville, Tenn., in the Chair.

Presidential Address: The Relation of Lipoids to Immune Reactions.—Dr. James W. Jobling, of Nashville, stated that the relation lipoids bore to immune reactions had been studied extensively during the past few years, but in this review it would be impossible to give more than a brief summary of the work. The relation of lipoids to biological phenomena did not receive much consideration until Meyer and Overton suggested their possible importance; they stated that the cell wall was composed chiefly of lipoids, a view that had been held for plant cells for a number of years, and, if this view was accepted, they must concede the possible importance of lipoids in protecting bacteria and the cells of the body against antagonistic substances. With regard to the resistance of bacteria to injurious agents, Petersen and the speaker had shown that bacteria were protected from the action of ferments by the unsaturated fatty acid compounds present in the cells, and that oxidizing agents such as iodine, hydrogen peroxide, etc., would destroy this protective action. It had been known for some time that many oxidizing agents had a bactericidal action. Bacteria might be so situated as to become inaccessible to the agents that normally brought about their destruction. This was particularly true in tuberculosis and syphilis, where the necrotic and avascular tissues surrounding a focus might be such as to prevent the entrance of immune substances, or other bactericidal agents. Their demonstration that the failure of autolysis was due to the protective lipoids made this phase of the subject more accessible to attack. They had shown, in addition, that oxidizing agents such as iodine inhibited the action of the antiferments, accelerated autolysis, and, as a result, exposed the infecting organisms to attack from without. The differences in results obtained by the various investigators suggested that lipoids in certain combinations might act as antigens, while the pure lipoids did not have this property. This might explain why the protein free lipoids of tapeworms and tubercle bacilli acted as antigens. It had been shown by Stuber, Dewey, Nuzum, and others that certain lipoids inhibited phagocytosis. What Graham observed suggested that the inhibition of phagocytosis was not due to injury of the cells. Muller concluded that bacterial lipoids were unimportant in the process of phagocytosis. Stuber believed that the agglutinins were produced as a result of the stimulus afforded by the fats liberated after destruction of the bacteria. Stuber also found that immune serum extracted with ether lost most of its agglutinating power, and that normal serum to which the ether extract had been added acquired an agglutinating value almost equal to that of the immune serum from which the extracts were obtained. Graham stated that ether anesthesia did not affect the agglutination titre of serums. Petersen and the speaker found that soaps injected intravenously into guineapigs in proper doses produced the symptoms and post mortem findings of anaphylaxis. It had been known for some time that the serum antitrypsin was increased after the recovery from anaphylactic shock, and with this in mind Peterson and the speaker investigated, first, the action of lipoids when given with the intoxicating dose of antigen, and, secondly, the influence of increasing the antitryptic power of the serum and the addition of soaps to an intoxicating dose, enabled the animal to resist several times the amount of the specific protein fatal for the controls, while a smaller dose of the antigen was required when lipoid free proteins were used Petersen and the speaker had shown that the removal of lipoidal antiferments from serum permitted the formation of toxic substances which they had termed "serotoxins." These toxic substances were formed through the action of the serum proteases on the serum proteins as soon as the protective lipoidal substances were removed.

Until recent years the entire focus of attention of immunologists centred about proteins and the chemistry of proteins. This was natural considering the remarkable development of protein chemistry that occurred during the time when immunology was in its infancy. At present, however, they had come to realize that the lipoids of the body were of far reaching consequence in almost all vital cellular phenomena, and to the realization of this fact the work of Funk had contributed materially. When contrasted with the relatively inactive protein molecule, the lipoids and fats stood out particularly by their great reactiveness, both physical and chemical. The rapidity with which colloidal changes could occur, the ease with which the water insoluble forms might saponify and become soluble, the intersolution of one form in the other, the frequent occurrence of combinations of proteins and lipoids, were all factors that tended to explain the constantly manifest influence of the lipoids in the various immunological and physiological balances. These considerations indicated that the fats and lipoids might play an important role in at least some of the immunity reactions.

Additional Facts Concerning the Protein Poison.—Professor Victor C. Vaughan, of Ann Arbor, Mich., stated that since his last publication on this subject, the following facts had been ascertained by his students and himself: 1. Casein yielded a large percentage of the protein poison. 2. The protein poison after the removal of all traces of mineral acid was strongly acid in and of itself. 3. The protein poison did not give the ninhydrin test, but did so after being split up with acid. 4. The poison gave a skin reaction in all persons. 5. The poison was not without harm when administered by mouth. 6. Animals might be acutely or chronically poisoned by oral administration. 7. In chronic poi-

soning by feeding, extensive fatty degeneration resulted. 8. The protein poisons from diverse proteins were not identical. 9. The protein poison from casein combined with certain unbroken proteins. In this combination the acidity of the poison was neutralized and its physiological action diminished. 10. From the tissues of animals killed with the protein poison, it might be extracted with acidified alcohol, and its presence demonstrated an amount roughly estimated by intravenous injections of guineapigs.

Inadequacy of the Anaphylatoxin Theory of Anaphylaxis.—Dr. Richard Weil, of New York, limited the discussion to the consideration of anaphylatoxin in the sense originally intended by Friedberger, namely, the product of the incubation of antigen and antibody in the presence of serum. The characteristic features of the test tube reaction were: 1. It took place not only through the interaction of an immunological couple, namely, antigen and antibody, but of entirely unrelated serums; 2, the two factors must be in certain definitely limited quantitative relationships; 3, it was slow and gradual; 4, it required the presence of complement. In every one of these features it differed from the anaphylactic reaction in the living animal or in the suspended uterus. The crucial test consisted in the fact that it was impossible to produce the anaphylactic reaction in the animal by conditions which duplicated those in the test tube, namely, the simultaneous intravenous injection of the two factors, antiserum and antigen.

According to the physical theory, the reaction was simply an expression of the alteration of cellular equilibrium which resulted when external antigen was brought into contact with cellular antibody. The characteristics of the reaction were all entirely in keeping with this interpretation. The precipitation reaction in the test tube, which was not accompanied by the chemical destruction of either factor, was: 1. Immediate; 2, proceeded in the absence of complement; 3, required relatively large amounts of antibody and relatively minute amounts of antigen.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 6, 1916.

The President, Dr. Walter B. James, in the Chair.

(Concluded from p. 573.)

The Influence of Alcohol on Man, with Special Reference to Psychological Effects *(Continued.)*—Dr. Charles R. Stockard, of Cornell University, spoke from the point of view of animal experimentation, and gave a few of the results of such experimentation, in the past eight or nine years, on the effect of alcohol on the developing embryo and on the descendants of animals treated with alcohol. In order to study the chemical effect of alcohol on the development of human offspring of those addicted to its use, it was necessary first to study its effect on animals. It was of vast importance to know how the children of alcoholic parents were affected and whether the taking of alcohol by the pregnant woman endangered the makeup of the child.

The first experiments were made on the eggs of fishes and of hens. In the former, the eggs were placed in a weak solution of alcohol and water and the eggs never developed normally, the abnormalities being confined chiefly to the central nervous system, while ninety per cent. had eye abnormalities. Magnesium chloride had much the same effect. Hens' eggs, if placed over a funnel containing alcohol fumes for a few hours before incubation, developed into abnormal chicks.

The question of whether the embryo developing within the body of the mother could be affected by the mother being treated with alcohol, was solved by experiments on guineapigs; this also applied to the effect on the offspring of the father being treated so as to change his cells. The effect of alcohol was watched on five generations and comparisons were made with the offspring of the same strain, which were not treated, as well as of other strains. A father treated with alcohol was mated to an untreated mother and vice versa; of one generation of offspring the father or the mother or both were treated; the untreated offspring of the first descendants of a treated father or mother were mated, but only the one generation was treated. There resulted an abnormal number of abortions, stillbirths, and abnormalities, and there was also much abnormal sterility among the children, grandchildren, and even great grandchildren from alcoholized ancestors. The worst complications resulted from the inbreeding of animals poisoned; they were dwarfs, deformities, animals with paralysis agitans, cyclopean monsters, and blind ones. Fifteen per cent. of inbred descendants from alcoholics were defective; some had no eyeballs, others had only one eye, lacking also the optic nerve, the optic tract, and optic fibres.

It was not held that these experiments could be transferred to man; they were made to see if it was possible to control embryonic development, whether defects due to alcohol could be transmitted by male or female or both, and it had been shown that such effect was possible whether it occurred in man or not.

Dr. Bernard Sachs, of New York, said that he could not be expected to discuss the addresses previously made, as everyone must have been benefited by hearing them and he admired their originality. If anyone believed alcohol innocuous, Doctor Stockard's experiments would disprove such belief. As a clinician, he was interested, as well as the laboratory workers, in the effect of alcohol, and he shared the belief that unless the body was sound the individual could not prove himself efficient. It seemed in order to call attention to one or two facts of importance. A few months ago, there was a symposium at the academy on syphilis in its relation to disease, and alcohol was the subject of tonight's; both these severe poisons had an effect on the nervous system. In regard to alcohol, it was unfortunate in one respect that it was not possible through laboratory experimentation to discern, as in syphilis, the early effects on the nervous system; at the present time, by examining the spinal fluid of the person suspected of syphilis, a diagnosis could often be established before the poison had brought about any actual changes. That was not the case with alcohol

unless the disease had reached the stage where positive symptoms appeared.

In view of the interesting statements of Professor Benedict, it was possible that some day the reaction time of alcoholic persons might give early warning of impending changes just as did the cytological changes in the cerebrospinal fluid and there might thus be given a clue to the early inroads alcohol made on the human system. There was one thing about alcohol which made it in a sense worse than syphilis; syphilis began as an exudative process whereas alcohol inaugurated a destructive process; it produced degenerative disease more effectively and chronically than syphilis and the effects were as noticeable from long continued use of moderate doses as from the occasional use of excessive doses. Another unfavorable point was that the signs and symptoms were noticeable long after the habit ceased.

The reason why alcohol was indulged in to such a great extent was the need of occasional stimulation. For certain duties and for the continuation of work, the ordinary fatigue of the day had to be neutralized in some way, and for this purpose many resorted to alcoholic stimulants, beginning with small doses. The habit was then continued until it was difficult to break. It would be well if it were more generally known that the best substitute for alcohol was coffee, which would give the desired immediate stimulation. On the whole, coffee was not injurious, though even that might be continued until it became a pernicious habit. It was to be regretted that coffee had been so maligned, and that its value as a stimulant had been greatly underestimated.

Dr. Haven Emerson said that, though impartiality had been advised in the discussion and in the analysis of the facts presented by the laboratory experts, it was difficult for any physician to be impartial if he had treated in homes, dispensaries, or hospitals the victims of alcohol. When the title of the Bureau of Infectious Diseases was changed to the Bureau of Preventable Diseases, it indicated a change in the point of view which had been going on throughout the country in the interests of public health. If they considered the possibility of the prevention of congenital defects of infants due to the use of alcohol by the parents, they must admit that it was within the sphere of public health officials to take up the propaganda against alcohol. It was admitted that the death rate from infectious diseases was higher among alcoholics; infectious diseases were more easily acquired by alcoholics, and recovery was in a smaller ratio among them. This was strikingly illustrated in pneumonia, typhoid fever, and septic conditions. The incidence of diseases due to alcohol itself and the results from its use in diseases of the central nervous system and of the assimilative organs justified an energetic campaign against its use. The question of economic efficiency could not be considered as part of the public health, yet the attitude of large employers of labor indicated that they were in accord with all efforts to diminish the use of alcohol, whether from an altruistic point of view, or from the standpoint of profit and loss.

Dr. Frederick S. Lee reported the results of his experiments on the action of alcohol on muscles. He spoke of the conflict between the two schools of pharmacologists regarding the action of alcohol on the central nervous system, Binz holding that the drug in small doses augmented the activity of nervous tissues and in large doses depressed it, while Schmiedeberg believed that there was always a depressing effect, whatever the quantity of the drug. In conducting his own experiments, which were performed with the aid of Salant and Levine, frogs were selected as subjects. One thigh was ligated in order to obtain a control muscle, and a solution of ethyl alcohol was then injected into either the stomach or the dorsal lymph sac. One half or three quarters of an hour later, the frog was killed and both gastrocnemius muscles, one normal and one alcoholized, were removed and stimulated until exhausted. It was found that alcohol in small doses increased the working power of the muscle, the results being shown in both a lengthening of the working period and an increase of the total work performed; but in large doses it diminished the working power. The same result was obtained after the animal had been given a dose of curare which paralyzed the nervous supply of the muscles. Under such circumstances, the action of the alcohol was purely muscular.

The most probable explanation of the results seemed to be that, in small quantity, alcohol might be used by living tissue as a food and a source of energy; but, in larger quantity, its toxic action predominated. Only when the physiological action of this peculiar drug on all the bodily tissues was fully analyzed and understood, would the essential data be in hand for a complete solution of the problem.

Dr. John H. Kellogg expressed his appreciation of the invitation to make a few remarks on the absorbing subject of alcohol, from the depths of his experience both at the Battle Creek Sanitarium, with chronic invalids from the pernicious effects of alcohol, and in connection with settlement work in Chicago. From his observations, he felt that it would eventually be proved that it was entirely possible to dispense with alcohol as a drug, as the results sought could be better obtained in other ways, and the great increase in chronic disease in this country could to a large extent be attributed to alcohol, especially the increase in diseases of the heart, bloodvessels, etc. Doctor Lee's experiments hardly seemed to have a direct bearing on the subject of the use of alcohol by human beings, as they showed the effects of alcohol on muscle only, and not on the nerve centres and the nerves themselves, and might be due to increase of muscle irritability. The experiments of Parkes and others had shown that alcohol in ordinary doses decidedly diminished man's working capacity.

Dr. Abraham Jacobi said that so many diverse opinions had been expressed that one or two more would not be amiss. He had felt in listening to Doctor Stockard that there could be no doubt of the affirmative answer of those guineapigs, could they reply to the question, To be, or not to be.

His experience of over fifty years in practice gave strength to his positive assertion that there was no remedy to equal alcohol in cases of mixed infection. There were septic diseases that could not be treated or cured unless large doses of alcohol were given. Mixed infection in diphtheria could not be cured by antitoxin, but treated with large doses of alcohol the sufferers might be saved. He had seen many such living, dying, or moribund patients since 1858, who had recovered absolutely through taking whiskey; they were not guineapigs, however, but human beings.

Letters to the Editors

AUTOINOCULATION IN POLIOMYELITIS; A RENEWED CRITICISM OF THE METHOD.

NEW YORK, *September 16, 1916.*

To the Editors:

My knowledge of "autoinoculation" was derived from the statement in the *Bulletin* of the department of health for August 12th, which read that the method "consists of using the fluid withdrawn by spinal puncture for reinjection subcutaneously or intramuscularly into the same patient." I assumed that a small quantity of fluid was withdrawn and this entire quantity reinjected. I therefore restricted my critical remarks (JOURNAL, p. 477) to the lack of experimental foundation and the inadmissability of the method, omitting discussion of the clinical soundness of the conclusions drawn from the results obtained by the procedure. Now, in this week's JOURNAL (September 16th) Doctor Agar tells us that the treatment "consists in drawing off from fifteen to sixty, seventy, or even a larger number of c. c. of spinal fluid and reinjecting into the muscular tissues from 0.5 to two or three c. c. of fluid." He tells us further that "in a number of instances the treatment was followed by marked improvement, reduction in temperature, and partial return to consciousness." So, then, Doctor Agar ascribes "the marked improvement, etc.," in his procedure exclusively to the reinjection of "0.5 to two or three c. c. of the fluid" and designates this procedure as a method of autoinoculation, neglecting entirely to take into consideration the possible effect of the withdrawal of relatively large quantities of spinal fluid. This statement was quite a surprise to me. I am sure that I am conservative in my estimate, when I state that eight out of every ten competent clinicians would be equally sure in their conclusion that the marked improvement and partial return to consciousness—not to speak of the reduction in temperature—which occurred in a number of instances, was due to the withdrawal of "fifteen, sixty, seventy, and more c. c." and that the improvement may have occurred *in spite of* the reinjection and not *because of* it. Why did Doctor Agar neglect to test his notion by the elementary procedure usually practised in investigations of this kind, namely: 1. By withdrawing only the small amount of the spinal fluid which is to be reinjected and wait for results; and, 2, by withdrawing aseptically sixty or seventy c. c. of the spinal fluid, putting it aside in a refrigerator, and twenty-four or forty-eight hours later, when no improvement followed, injecting two or three c. c. of it? If marked improvement had followed these injections, there would be at least some logical support for the hypothesis of the therapeutic value of autoinoculation. Furthermore, how soon after the autoinoculation did the "marked improvement, etc.," set in? If it had set in four or five days after the injection, I doubt that Doctor Agar himself would ascribe the improvement to the injection. If, on the other hand, the improvement had already set in on the next day, nobody who knows anything about immunity would ascribe the improvement to the intramuscular or subcutaneous injections of the previous day, because we do not deal here with passive immunization, but with an attempt to produce active immunization in a disease in which, even after an intracerebral injection, the incubation time is pretty long. Moreover, it is a well known fact that in active immunization during the first two or three days after an injection, the immunity is rather definitely *decreased*. It is therefore obviously very difficult to connect the improvement observed with the autoinoculation. Finally, what does "a marked improvement, reduction of temperature, and *partial return to consciousness*" signify in a disease in which the mortality even under the "expectant" method of treatment is comparatively low? Under these circumstances, Doctor Agar was surely justified in becoming, as he says, "personally very skeptical of the real value of autoinoculation," in spite of his experience that "many of the families in which autoinoculation has been used, and many of the physicians who have used it are enthusiastic about the results."

Now as to the possible harm which the autoinoculation may do. From his letter in the JOURNAL I learn that Doctor Agar injected the spinal fluid exclusively into the *muscle tissue*. Here I agree with him that the small quantities which he used have probably done no harm. Auer and I have shown in several communications that the effect of an intramuscular injection is practically equal to that of an intravenous; and we know that in order to produce poliomyelitis experimentally by intravenous injections, large quantities of virus must be used. But the statement in the *Bulletin* which induced me to write my first criticism speaks of "reinjections *subcutaneously* or intramuscularly," and in my letter to the JOURNAL I criticised exclusively the subcutaneous injection. Most practitioners and medical writers do not yet distinguish between intramuscular and subcutaneous injections, and as a rule they practise rather the latter form. As far as the subcutaneous injection is concerned, I wish to repeat emphatically my former dictum, namely, *"that such therapeutic experiments should not be made on human beings!"*[1] Doctor Agar says that I "failed to mention the fact that the experimenters who have endeavored to inoculate monkeys by intramuscular injections have reported that it is difficult and in some instances impossible to produce a general infection in this way." But my statement reads that *"subcutaneous* injection of live virus is *often* capable of setting up an injection of poliomyelitis." This was based on the following statement of Flexner and Lewis: "Our impression is that infection is *readily* accomplished by way of subcutis" (*Jour. Exp. Med.*, XII, p. 241). Doctor Agar says further that I assume "that a larger number of organisms are being introduced *into the system* than there were previous to the treatment." Of course, I never said and could not have assumed it, since in any event no more organisms could have been injected subcutaneously than were withdrawn from the spinal canal. But my objection was not based upon the assumption that a larger number of organisms were being introduced into the system. I said: "The first effect of an injection into a patient of a medium containing live virus, while the disease is still in an active state, will not be an immediate active immunization, but an *additional infection.*" Perhaps I had better try here to elucidate my statement by the following admissible suppositions:

1. The virus contained in the spinal fluid of an individual, sick with poliomyelitis, although very toxic when introduced into the spinal canal and in the fresh spinal fluid of a normal individual, may, while still present in the spinal fluid of that sick individual, be more or less restrained in its toxic action upon nerve cells of the patient, and for a variety of reasons: First, surviving nerve cells of the surface of the cord which is continuously in contact with the spinal fluid, may have acquired a degree of resistance to the virus. Second, on account of the inflammation and the occlusion of many of the capillaries, the virus may not readily get at the nerve cells. Finally, the virus may have *lost some of its toxicity* and may need the contact with fresh normal tissue for *reactivation*.

2. When injected subcutaneously, the virus finds there fresh tissue and fluid for *activation*, and from here even two or three c. c. may cause an additional infection by getting into nerve cells previously entirely unaffected. The experiments with subcutaneous injections of the virus of poliomyelitis were made exclusively on *normal* animals; the results may be entirely different, however, when the injections would be made *into sick animals*—experiments which, according to my knowledge, have not yet been carried out. It is assumed that in individuals, sick with polio-

[1] In a letter I received recently, the writer—if I understood the letter correctly—seemed to contemplate injecting fifty or seventy c. c. of spinal fluid subcutaneously!

myelitis, the *permeability of the choroid plexus is increased,* and therefore the injected two or three c. c. of the freshly activated spinal fluid may, indeed, pass rapidly into some new and vital spots of the central nerve system and thereby cause more extensive paralysis or even death.

I am aware that these suppositions are mere hypotheses; but they are perfectly admissible ones and can and ought to be tested by experiments on animals before attempting to use this method on human beings. The latter must always get the benefit of any doubt, and surely that of a reasonable doubt.

Furthermore, while I am inclined to believe with Doctor Agar that no harm was actually done by his *intramuscular* injection, I cannot see that there is definite evidence for such a positive assertion. Suppose that some one took up the opposite attitude, namely, that in the instances of Doctor Agar in which the treatment was followed by a *partial* return to consciousness, the patients would have returned to full consciousness and have remained alive, if some of the spinal fluid had not been reinjected; or that a certain residual paralysis would, without the autoinoculation, have been less extensive—what evidence could be brought forward to refute such an assertion?

On the basis of the foregoing I am therefore of the opinion that: 1. *There is no evidence that autoinoculation is serving any useful purpose;* and, 2, *that the method may actually do harm.* Furthermore, there is no positive evidence sufficient to refute a statement that it actually has done harm.

I thoroughly disagree with Doctor Agar when he says, "These observations could be much more readily made in human beings than in monkeys, and under the circumstances I consider the trial justifiable." I hold the opposite view, namely, that *no therapeutic procedure or remedy should be tested on human beings before it has been well studied on animals.* Even those who master their subject, let us say, immunity, should not take anything for granted before it has been established by animal experimentation.

In one point I willingly accept the statement of Doctor Agar, namely, that he was not *prohibited* by the health department to carry on the autoinoculation treatment. My information to that effect I received from the department in a message by telephone which I may have misinterpreted.

One statement of Doctor Agar has been a surprise and a disappointment to me, namely, that *it now appears that the convalescent serum has little or no value.* By newspaper reports we were led to believe that this treatment gave nearly 100 per cent. success in another hospital under the control of the health department.

S. J. Meltzer, M. D.,
Rockefeller Institute.

[With this letter we must regretfully bring the discussion to a close; we feel that ample opportunity has been given to advance every argument pro and con.—Eds.]

THE TREATMENT OF POLIOMYELITIS: A NOVEL METHOD.

Seattle, Wash., *August 14, 1916.*

To the Editors:

Infantile paralysis is caused by inadequate maintenance of calcium and phosphorus absorption, the usual sources of which are fresh eggs, raw milk, whole grains, fresh fruits and vegetables; and depleted by climate, environment, stress.

Contributing causes are, 1, lack of money to meet exigencies of distribution of fresh foods; 2, lack of advice of men properly trained in Materia medica.

New York cannot cope with the situation because medical efficiency is sidetracked by bacteriophobia. Health boards are dominated by politicians rather than physicians. To hold their jobs, they must worship at the shrine of Bacterium.

Such men were described by Mirabeau as "bonzes who despise medicine, consider therapeutics a low charlatanism, and whose whole life is devoted to chatter of congresses and to intrigues of salons and academies."

Bugs are not superhuman any more than witches are. Man is a superbug, becomes so by concentrated acquisition and harmonious exercise of organized calcium and phosphorus, the most essential elements of brain and cord structure. By the loss of these, or of the capacity for exercise of them, he loses his supremacy and reverts to a lower type of organism.

Resistance against diseases generally classed as infectious or contagious, can be, and is provided by the internal administration of calcium carbonate alternating with phosphoric acid—perfectly safe if intervals are four or more hours.

Calcium carbonate should be given with, 1, such alimentary antitoxins as calomel, camphor, ipecac; with, 2, such assimilants as magnesium oxide and potassium nitrate; and with, 3, such correctives (of nausea, stagnation) as rhubarb, senna, anise, coriander, opium, belladonna, nux vomica. W. M. McDowell, M. D.

DOGS AND INFANTILE PARALYSIS.

New York, *September 11, 1916.*

To the Editors:

The papers today record on medical authority that a dog has died of infantile paralysis. If this is true, the disease could be carried to children by either mosquitoes or fleas that had bitten the dog and then bitten children. In the epidemic of bubonic plague in Siam, in 1905, there was an enormous and disproportionate death rate among children in the town of Pechaburi. This was traced by me to the fact that the rats infected by plague had all died. As soon as the bodies became cold the infected fleas deserted them and took up their habitat on the pariah dogs. Petting these dogs, the children were bitten by the fleas and died of bubonic plague in great numbers. So any mosquito or flea biting an animal having infantile paralysis, and subsequently biting a child, would transmit the disease. The board of health of New York is doing one thing of greater value than any other undertaken to stamp out infantile paralysis in this epidemic, and that is the atomization of mineral oil in the rooms of the public schools. This will kill all of the mosquitoes, fleas, flies, bedbugs, and roaches there.

In this way the parasites were fought in the bubonic plague epidemic in Siam, in 1905, where the oil was sprinkled over the floors by watering pots; oil was atomized also in Serbia in the epidemic of typhus fever, last year, in order to kill the lice on the bodies and clothing of the Serbians. Charles S. Braddock, Jr.,
Late Chief Medical Inspector,
Royal Siamese Government.

RAW EGG ALBUMIN

Buffalo, N. Y., *September 12, 1916.*

To the Editors:

Your quotations from Bateman's article in the *Journal of Biological Chemistry* and your editorial comment on the utilization of egg proteins, deserve commendation. Our knowledge regarding the subject is not very recent, so far as practical matters are concerned, but, like pepsin and starch indigestion, it seems to permeate the profession very slowly. For instance, in a book on dietetics published in 1908 and, of course, prepared somewhat earlier, I made the following statements: "While caseinogen is the only instance of a proteid normally coagulated by the body, egg albumin is a somewhat analogous, unique instance of a substance which, if given in considerable quantities—five or six egg whites or more—is eliminated to some degree, as a foreign substance, by the kidneys." The reputation of eggnog, a raw custard reinforced with whisky or brandy, is exaggerated. The raw egg albumin is not so likely to be assimilated as the cooked. . . ." In an earlier book, published in 1904, is the following statement: "Raw egg albumin introduced into the circulation or even into the stomach in considerable amounts is excreted unchanged by the kidneys, at least in part." It should be understood that no claim of originality, explicit or implicit, was made for these expressions.

It may be allowable to express the further opinion, based on clinical and experimental observations, that hard boiled egg albumin is not especially difficult of digestion if moderately well chewed or comminuted. I have not, however, noticed a tendency to diarrhea from reasonable amounts of eggnog or other forms of raw egg, except to the degree to be expected from any sweet, liquid food.

A. L. Benedict, M. D.

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Roentgenographic Diagnosis of Dental Infection in Systemic Diseases. By SINCLAIR TOUSEY, A. M., M. D., Consulting Surgeon to St. Bartholomew's Clinic, New York. Published by Paul B. Hoeber, New York City.

Since pyorrhea has been found to be the cause of so many systemic conditions the etiology of which has long been a matter of doubt, any contribution to the subject must of necessity be of great interest. In making the diagnosis of pyorrhea, the x ray is of the greatest assistance, as through its agency any source of infection connected with the teeth or the pneumatic sinuses of the face can be revealed. In this small volume Doctor Tousey has set forth the numerous conditions which may have pyorrhea as their cause, and the x ray pictures which it contains make it one of the most valuable additions to the literature on this particular subject.

Hay Fever, Its Prevention and Cure. By W. C. HOLLOPETER, A. M., M. D., LL. D., Attending Physician St. Joseph's Hospital; Pediatrist to the Philadelphia General Hospital, etc. New York and London: Funk & Wagnalls Co., 1916. Pp. 347. (Price, $1.25.)

In this little volume will be found practically all that is known about hay fever, its history, causes, periodicity, symptoms, pathology, diagnosis, prognosis, and treatment. Under the last heading will be found a discussion of preventive treatment, local treatment, diet, exercise, rest, serums, phylacogens, calcium salts, pollen therapy, and surgical measures. The book closes with an extensive bibliography. The author has certainly been industrious in bringing together most of what has been written on the subject, and we think that he is unduly handicapped by the publishers, who announce that this is "a book for laymen as well as for physicians." Our experience is that books intended for both of these classes of readers are of real value to neither.

The Sex Complex. A Study of the Relationships of the Internal Secretions to the Female Characteristics and Functions in Health and Disease. By W. BLAIR BELL, B. S., M. D., Lond., Examiner in Gynecology and Obstetrics to the University of Belfast and to the Royal College of Surgeons, England, etc. New York: William Wood & Company, 1916. Pp. xvii-233. (Price, $4.)

The phenomena of sex have become the subject of a vast amount of recent literature. How radical the differences are which students expect to find between the sexes may be judged by a remark of the author of this book (p. 17), viz.: "Some day, perhaps, we shall be able to base our knowledge of these physiological and morphological dissimilarities on the variations to be found—both quantitative and qualitative—in the primary sex characteristics of the endocritic organs." Some gross distinctions already known are that the human male uses more oxygen than the human female, and that in men the blood has a higher specific gravity, more red corpuscles, and a higher percentage of hemoglobin than in women. What will suffragists say to the statement in this deeply scientific work that, while man shows a tendency to psychical domination and certainty, woman is psychically dependent and hesitant? The work of Professor Bell comprises a study of the relationships of the internal secretions to female characteristics both in health and disease. The study of the parathyroids, the pineal, and the thymus is incomplete, owing to the outbreak of war; this is to be remedied in a future book. The author is to be congratulated on the lucidity of his exposition, which makes the book interesting to the general medical reader. The effects of excess and of insufficiency of each ductless gland are taken up in turn. A chapter is devoted to the sexual psychoses, and emphasis is laid on the fact that insanity may depend on the state of the internal secretions—something, the author says, that has been staring alienists in the face, but which they failed to recognize. Excessive ovarian secretion, for example, may lead to various moral irregularities. There is a short appendix devoted to the physiological effects of extracts of the endocritic organs.

This is an entertaining as well as a suggestive work and throws much new light on the psychology of women. Physicians should read it, for it contains information not likely to be elicited from even the most intimately known patient and yet essential to the comprehension and diagnosis of many an obscure case. Probably only women physicians are likely to hear individual confessions which will corroborate many of the general statements of Professor Bell.

Interclinical Notes

The pictures in *Leslie's* for September 7th are unusually good and exciting; the survivors of the great war will have received a remarkable training in facing emergencies, which ought to stand them in good stead in their future civilian life—that is, if they do not die of old age in the army. An unusual sort of picture shows Canadian trained nurses beating their military patients in short distance sprinting at Woolwich, England. Interesting details of the life of our boys along the Mexican border are given.

* * *

A picture of the great war has appeared in many American papers entitled The Fighting Fifth after the Battle of St. Eloi. It shows a regiment singing, cheering, and laughing, adorned with the spoils of the enemy, evidently quite hysterical with good humor, despite the fact that their numbers have been more than decimated by the battle just concluded. This is precisely the horrid fascination of warfare, this intoxication of the hand to hand fight, which will bring men from anywhere, from peace and luxury, at the call of the authorized commander.

* * *

Richard Watson Gilder practically revolutionized the manners and customs of editors; he assumed all responsibility for the contents of his magazine and made the entire staff eat out of his hand. This is told in the September *Century* in a series of his letters collected and edited by Rosamond Gilder; these letters make mighty good and comforting reading for editors, and should be read by authors also, to whom they will reveal many strangely human qualities with which they have not been disposed to credit editors. Fewer manuscripts than now were turned out in the good old Gilder days, which gave him an opportunity to write individual letters of rejection, many of which must have proved priceless to the recipients.

* * *

Thomas J. Riley, general secretary of the Brooklyn Board of Charities, tells in the *Survey* for July 29th, what he saw during a walk through that borough that seemed to hold some causal relation with the epidemic: Tenement houses of all kinds, Italian, Syrian, and Scandinavian communities, the water front with its shipping from all parts of the world, communities settled at the foot of hills, streets filled with small shops, streets with car lines, streets with push carts, streets which children and even adults used for recreation and other social purposes, dirt of various kinds. Negroes seemed to be exempt. Is infantile paralysis due to the same causes as give us tuberculosis, poverty, ignorance, deformity, delinquency, and drunkenness?

* * *

Despite Kipling, we are not sisters and brothers under our skins; this is proved by the queer phenomena of protein sensitization, which vary from one individual to another in a strange way. So far, we believe, only one house manufactures the soluble proteins used in the test—the Arlington Chemical Company, of Yonkers, which gives details in its circulars. Only recently it has been discovered that the merest trace of an unwelcome food may produce in one case acute swelling of the tongue, pharynx, or esophagus, in another severe bronchial asthma, in a third vomiting, diarrhea, or abdominal pain, in a fourth urticaria, angioneurotic edema, eczema, or erythema. Such sensitization will some day be discovered in childhood and much suffering will be avoided.

Meetings of Local Medical Societies

Monday, *September 25th.*—Poughkeepsie Academy of Medicine.

Tuesday, *September 26th.*—New York Psychoanalytic Society; New York Dermatological Society; Onondaga Medical Society, N. Y.; Valentine Mott Medical Society, N. Y.; Medical Society of the County of Chautauqua, N. Y.

Thursday, *September 28th.*—Ex-Intern Society of Seney Hospital, Brooklyn; Medical Union, Buffalo.

Friday, *September 29th.*—New York Society of German Physicians; Manhattan Medical Society; Italian Medical Society of New York.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending September 13, 1916:

Foster, M. H., Surgeon. Directed to proceed to Washington, D. C., for conference relative to poliomyelitis.

Fox, Carroll, Surgeon. Directed to proceed to Denver and such places in the State of Colorado as may be necessary for the investigation of health organization and administration.

Hurley, J. R., Passed Assistant Surgeon. Relieved from duty at Philadelphia, Pa., and directed to proceed to Baltimore, Md., for duty in the prevention of the interstate spread of poliomyelitis.

Lavinder, C. H., Surgeon. Granted one day's leave of absence, September 9, 1916, under paragraph 193, Service Regulations.

Lombard, M. S., Assistant Surgeon. Granted leave of absence for one month, from October 20, 1916.

Olesen, Robert, Passed Assistant Surgeon. Granted leave of absence for the period October 2 to December 4, 1916.

Schereschewsky, J. W., Surgeon. Detailed to deliver an address before the American Chemical Society, at New York, N. Y., September 21, 1916, stopping en route at Scranton, Pa., to present a paper on occupational diseases before the Pennsylvania State Medical Society, September 20, 1916; also detailed to institute an investigation of occupational diseases incident to chemical industry in several States east of the Mississippi River.

Tanner, W. F., Assistant Surgeon. Relieved from duty at Columbia, S. C., and ordered to proceed to Spartanburg, S. C., for further duty in investigations of pellagra.

Voegtlin, Carl, Professor. Relieved from duty at Spartanburg, S. C., and ordered to return to station at Hygienic Laboratory, Washington, D. C.

Warren, B. S., Surgeon. Directed to proceed to Spartanburg, S. C., for conference with officer in charge of studies of pellagra, with special reference to economic and budgetary data.

Wildman, H. V., Jr., Assistant Surgeon. Detached from Coast Guard cutter *Seneca*, and directed to report to Division Commander U. S. Coast Guard, Tompkinsville, N. Y.

Appointments.

Dr. Edwin Owen Woods, Dr. Joseph Duerson Stout, and Dr. Clifford Rush Eskey appointed and commissioned as assistant surgeons, from date of oath, August 18, 1916.

Casualty.

Surgeon R. H. von Ezdorf died suddenly near Lincolnton, N. C., September 8, 1916. Doctor von Ezdorf was born in Philadelphia, August 13, 1872, and graduated from the medical department of George Washington University in 1894. He was commissioned an assistant surgeon, March 2, 1898; was promoted to passed assistant surgeon five years later, reaching the grade of surgeon October 1, 1912. He served at various quarantine stations in the United States, Cuba, and at Panama, and had been engaged on numerous occasions in the suppression of yellow fever. At the time of his death, Doctor von Ezdorf was in charge of the malarial investigative and eradicative measures of the Service in the South.

Boards Convened.

Boards of commissioned medical officers convened September 18, 1916, for the purpose of examining candidates for appointment as assistant surgeons in this Service, as follows: Washington, D. C. Detail for the board: Assistant Surgeon General W. C. Stimpson, chairman; Assistant Surgeon General R. H. Creel, member; Assistant Surgeon General J. W. Trask, recorder. St. Louis. Detail for the board: Surgeon M. J. White, chairman; Assistant Surgeon K. E. Miller, recorder.

Births, Marriages, and Deaths

Born.

Lieb.—In Watkins, N. Y., on Monday, August 7th, to Dr. and Mrs. Clarence W. Lieb, a daughter.

Married.

Dunn-Martin.—In Hartford, Conn., on Thursday, September 14th, Dr. George Washington Dunn, of New Britain, Conn., and Miss Mary Isabel Martin.

Fraenkel-Wolska.—In New York, on Thursday, September 7th, Dr. Joseph Fraenkel and Madame Ganna Wolska.

Grady-Doherty.—In Worcester, Mass., on Monday, September 11th, Dr. Thomas H. Grady, of Clinton, Mass., and Miss Minnie Elizabeth Doherty.

O'Connell-Nugent.—In Holyoke, Mass., on Tuesday, August 29th, Dr. George B. O'Connell, of Lewiston, Me., and Miss Claire E. Nugent.

Whoriskey-McDonald.—In Cambridge, Mass., on Tuesday, September 5th, Dr. John J. Whoriskey and Miss Katherine E. McDonald.

Died.

Brede.—In Minneapolis, Minn., on Tuesday, September 5th, Dr. William G. Brede, aged forty years.

Dinkelspiel.—In New Rochelle, N. Y., on Monday, September 11th, Dr. Leo Dinkelspiel, of New York.

Duer.—In Odessa, Del., on Wednesday, September 6th, Dr. Edward L. Duer, aged eighty years.

Dwight.—In New Bedford, Mass., on Wednesday, September 6th, Dr. Henry L. Dwight, aged fifty-five years.

Hennessy.—In Bangor, Me., on Sunday, September 10th, Dr. Daniel Hennessy, aged seventy-nine years.

Leffingwell.—In Oswego, N. Y., on Sunday, September 10th, Dr. Elisha D. Leffingwell, aged sixty-six years.

Maddox.—In Stone Mountain, Ga., on Thursday, August 31st, Dr. G. W. Maddox, formerly of Birmingham, Ala.

Myers.—In Mount Vernon, N. Y., on Thursday, September 14th, Dr. Frances M. Myers, aged forty-six years.

Nunez.—In New York, on Friday, September 15th, Dr. Enrique Nunez y Palomina, of Havana, Cuba, aged forty-four years.

Parker.—In Winthrop, Mass., on Thursday, September 7th, Dr. George C. Parker, aged sixty-five years.

Preston.—In Pawtucket, R. I., on Friday, September 8th, Dr. John N. Preston, aged sixty-nine years.

Provost.—In Berlin, N. H., on Saturday, September 9th, Dr. Azarie Provost, of Lewiston, Me., aged forty-six years.

Smyth.—In Londonderry, Ireland, on Monday, September 4th, Dr. Andrew Woods Smyth, of New Orleans, La., aged eighty-three years.

Steele.—In Mongaup Valley, N. Y., on Sunday, September 10th, Dr. Wellington G. Steele, aged sixty-one years.

Stone.—In North Sutton, N. H., on Wednesday, September 6th, Dr. Eugene P. Stone, United States Navy, retired.

Stratton.—In Richmond, Va., on Wednesday, September 6th, Dr. Thomas E. Stratton, aged seventy-seven years.

Townsend.—In New York, on Wednesday, September 13th, Dr. Emma Albertina Walser Townsend, aged fifty-one years.

Turner.—In Hartford, Conn., on Saturday, September 9th, Dr. George H. Turner, Jr., of Portland, Me., aged thirty-eight years.

Wardell.—In Maplewood, N. J., on Thursday, September 7th, Dr. Percival G. Wardell, aged eighty-one years.

Willis.—In Somerville, Mass., on Wednesday, September 6th, Dr. Reuben Willis, aged seventy-four years.

INJURIES OF THE CHEST DURING WAR.

By R. MURRAY LESLIE, M. A., B. Sc., M. D.,
London, Eng.,

Senior Physician, Prince of Wales' General Hospital; Physician, Royal Hospital for Diseases of the Chest; Late Civil Physician, Hampstead Military Hospital.

The great majority of injuries of the chest in the present war are the results of gunshot and shrapnel wounds. It is quite exceptional to meet bayonet wounds in the base hospitals, probably because a large proportion of the wounded die on the field of battle. Crushing injuries of the chest from falling trench parapets, due to shell or mine explosions, are not uncommon.

Frequency of chest injuries. Inspector General Delorme of the French army, states that among ambulance cases chest injuries represent an average proportion of ten per cent., one third of which end fatally on the battlefield; while at the rear the proportion of chest cases is from six to eight per cent. When men are advancing the gunshot wounds they receive are generally transverse, in contradistinction to those received while lying prone on the ground, when they tend to be longitudinal in direction.

CLASSIFICATION.

Gunshot wounds of the chest are classified as nonpenetrating and penetrating, according to whether the chest wall only or the thoracic cavity with its contents, has been pierced by the missile.

A. *Nonpenetrating wounds of the chest.* The consideration of nonpenetrating wounds of the chest need not detain us long, for the questions involved are mainly surgical. Shrapnel injuries come under this category, the round bullets often lodging in the chest without perforation, and producing jagged, painful wounds, which are invariably septic. Glancing rifle bullet flesh wounds in the axillary and infraaxillary regions are quite common.

One or two points of medical interest deserve special mention. In the first place it is to be noted that the lung may be contused without actual penetration of its tissue by the missile, as the blow caused by the impact of a bullet on the bony wall of the thorax may produce a bruising of the lung substance immediately subjacent, resulting in a slight amount of infarction and consequent hemoptysis. Hemoptysis, therefore, is not a conclusive sign of lung penetration. The following case under the writer's care well illustrates this point:

CASE I. Private F. M., twenty-eight years old, while advancing in Gallipoli, was hit in the right chest by a bullet, which, fortunately, first struck a pocket camera in his right breast pocket. Several fragments of the camera and of the bullet casing entered the chest wall, some of which came away in the dressings, some could readily be felt under the skin, while others could be seen by the x rays to be lodged in the underlying muscular tissues. The patient expectorated blood for about an hour after being shot. There was absolutely no other evidence of injury to the pleura or lungs. (Fig. 1.)

Hemothorax may also occur without lung perforation, as the result of contusion or rib fracture, with laceration of intercostal or pleural vessels.

It may be well here to make a few remarks on the occurrence of shock and other functional disturbances in connection with wounds of the chest. Some authorities are of opinion that the degree of shock, even in the case of penetrating wounds, depends principally upon the damage done to the chest wall. The shock may be severe when the ribs or vertebral column are injured, while on the other hand, in the majority of gunshot wounds of the chest, there is remarkably little shock, as is illustrated by the following case:

CASE II. A young officer was shot in the chest by a sniper, the bullet producing, close to their angles, a comminuted fracture of the fourth and fifth ribs, from which it was deflected backward and outward, so that it passed between two spinous processes, emerging under the skin by an exit wound in the back, some inches to the right (opposite side) of the vertebral column. Notwithstanding this serious injury, the patient was able to get up in ten minutes and run to the dressing station some distance away, spitting blood all the time. (Fig. 2.)

Many similar cases, with little or no shock, have been recorded. Hypodermic injection of an efficient dose of morphine (one half to three quarter grain) is marvelously effective in relieving the pain, dyspnea, and shock.

Apart from gunshot injuries, the writer has had several cases of spinal concussion, followed by functional, or, more rarely, organic paraplegia, as the result of crushing injuries of the chest, e. g., being buried in the trenches owing to shell explosions. The functional paresis was generally bilateral. One patient, however, exhibited a unilateral condition, being unable to put one heel to the ground, owing to the involuntary contraction of the opposing group of muscles. Most of these

functional cases were instances of so called "defective inhibition of the antagonist group of muscles." One case exhibited symptoms suggesting spinal hemorrhage, with ankle clonus, extensor plantar response, anesthesia below a certain level, and other evidence of a sudden organic lesion of the cord.

B. *Penetrating wounds of the chest.* The effects of penetrating wounds depend upon two factors: 1. The direction and site of the bullet track; and, 2, the presence of septic material within the thoracic cavity.

1. *The direction and site of the bullet track.* The direction of the bullet track and the particular zone affected are of the utmost importance. Longitudinal wounds in the long axis of the body, owing to the tendency to cervical and abdominal complications, are more dangerous than those which are transverse, whether the latter be anteroposterior or lateral. As regards anteroposterior transverse wounds, the particular zone affected is all important. Wounds in the middle of the chest or central zone are extremely dangerous, and often immediately fatal, owing to the presence of the heart and pericardium, the great vessels at the root of the neck, and the large bronchi and bloodvessels at the roots of the lungs. Wounds of the peripheral or lateral zone involve least risk, for the bloodvessels and bronchioles in the lung substance are quite small. Wounds in the middle zone are more serious, for the bloodvessels and bronchi are of larger size, and the resulting hemorrhage is correspondingly greater. Lateral, transverse wounds are much less dangerous than one would imagine, and it is extraordinary with the modern, small, high velocity bullet, how often the important structures in the posterior mediastinum escape injury.

FIG. 1.—Case of nonpenetrating wound of chest with hemoptysis. Bullet struck a pocket camera, the fragments of which and of the bullet casing lodged in the chest wall. There was expectoration of blood for an hour after the injury, but no signs of involvement of pleura or lungs developed. (Radiograph by Mr. Shenton.)

It is important to remember that perforating wounds of the chest may exist without an external wound on the actual surface of the thorax. Thus, for instance, the entrance wound may be found in the neck, the bullet passing longitudinally into the chest behind the clavicle; or it may be situated in the upper arm, if that happens to be extended horizontally at the time of injury, the bullet passing into the chest beneath the skin of the shoulder or axilla; or it may be found in the abdomen or loin, the bullet penetrating the chest by way of the diaphragm. The writer had an Australian soldier recently under his care with pyohemothorax, in whom the entrance wound was represented by an extremely small scar immediately to the left of the second lumbar spine, the bullet—as shown with the x rays, and found on operation—lying below the eleventh rib, on the left side, in the pleural cavity.

2. *The presence of septic material within the thoracic cavity.* Round shrapnel bullets and shell fragments are much more likely to carry in infected material from the skin and clothing than the small, pointed, high velocity rifle bullets. Wide, gaping shell wounds naturally tend to facilitate infection, while wounds from ricochetting rifle bullets, which have been deflected by contact with the ground, are much more apt to be septic than those which have struck the chest directly. The question of intrathoracic sepsis is mainly of importance in connection with pleuritic effusions, and will be specially considered in connection with hemothorax and pyothorax. Curiously enough, although the entrance and exit wounds in the chest are generally septic, the bullet track in the lung appears, as a rule, to be sterile. Notwithstanding the presence of the heart and great bloodvessels, chest wounds are much less dangerous than abdominal wounds, owing to the absence of hollow viscera with septic contents.

The principal points of medical interest in connection with penetrating wounds of the thorax may be grouped under the following headings:

1. Injuries of the pleuræ and lungs.
2. Injuries of the heart and great bloodvessels.
3. Complicated injuries.

1. *Injuries of the pleuræ and lungs.* Pleural effusions are by far the most important phenomena in connection with bullet wounds of the chest, and these, in order of frequency, are: *a*, hemothorax; *b*, pyothorax; *c*, pneumothorax (air effusion), and *d*, simple serofibrinous pleurisy.

a. Hemothorax (hemorrhage into the pleural cavity) is such a common accompaniment that it may be considered as the distinctive clinical feature of penetrating wounds of the chest. It occurs in fully seventy-five per cent. of such wounds.

The source of the blood is still a matter more or less *sub judice*. Sir J. Rose Bradford states (*British Journal of Surgery*, III, p. 250) that the

exact source cannot be determined in life, but that every case should be treated as if the blood had been derived from the lung. He admits, however, that post mortem evidence has shown that in some of the cases the blood came from the vessels of the chest wall, and in others directly from the lungs. On the other hand, Mr. Keogh Murphy, in his recently published work, *Wounds of the Thorax in War*, makes the following statement: "All are agreed that hemothorax is the result of slow *bleeding from the chest wall*, through the parietal pleura, and that it does not come from the perforated lung." He speaks of a "gradual continued oozing from an intercostal vessel." Advocates of the latter view maintain that the small lung wound is almost immediately sealed by the puckering due to the action of the elastic lung tissue. On the other hand, the writer has seen a lung, post mortem, with a patent opening leading into the lung track, the latter being surrounded by an extensive blood infarct. In fractured ribs, particularly when the fracture is a comminuted one, the intercostal bloodvessels are almost certain to be torn across or lacerated, when we have the requisite conditions for hemothorax, apart altogether from injury to the lung.

Fig. 2.—Case of hemothorax treated by breathing exercises. Radiograph taken two months after injury. Note united fracture of fourth and fifth ribs on left side. Breathing exercises begun at the end of third week. Hemothorax not aspirated. No sign of effusion in six weeks. In two months' time the fluorescent screen showed perfect movement of the left diaphragm quite equal to that on the right side. N. B.—The dark line represents a wire passing partly round the chest and joining the entrance and exit wounds to indicate the line of the bullet track. (Radiograph by Doctor Knox.)

There is considerable difference of opinion as to the degree of clotting which takes place inside the pleural cavity. Th investigations of Captain Elliott and Captain Henry make it probable that clotting always takes place, and, as a rule, before the fourth day, through the action on the blood of a ferment liberated at the surface of the wounded tissues. These observers showed that the presence of the blood induces a certain amount of inflammatory effusion of fluid containing fibrinogen, and that a layer of compact fibrin is often found post mortem adhering to the pleural surface and closing the wound.

The clinical features of sterile hemothorax may briefly be described as follows: When the soldier is first wounded, he generally feels as if he had been suddenly "winded," and sometimes speaks of a momentary whiplike pain in the chest. He usually spits blood, and there is shortness of breath accompanied by a sense of oppression in the chest, which, in sterile cases of hemothorax, is well marked during the first two or three days, after which the dyspnea is scarcely noticeable in the recumbent posture, and there is then, as a rule, but little pain or discomfort. Fracture of the ribs aggravates the dyspnea. The writer has seen only one case of orthopnea with cyanosis, and in this instance the hemothorax proved to be an infected one, the symptoms being ultimately relieved by rib resection and evacuation. There is generally pyrexia of a mild type, oscillating between 98° in the morning and 101° or 102° F. in the evening. There is no blanching as in the case of other internal hemorrhages. After the first few days, the patient looks extremely well, and lies comfortably in bed. The physical signs are those of pleurisy with effusion, although, owing to the fact that collapse of the lung readily takes place, the phenomena of collapse play a larger part than in ordinary pleuritic effusions in modifying the orthodox clinical picture.

The following physical signs are worthy of special mention: There may be a considerable blood effusion, without much displacement of the heart; this is particularly the case after the first week, when the chest has become more or less immobile from pulmonary collapse. Retraction of the chest sets in earlier than in ordinary pleuritic effusion, and may be well marked in two or three weeks' time. Above the area of percussion dullness, there is frequently a distinct area of subtympanitic percussion —in reality, Skodaic resonance—due to the emphysematous expansion of the upper lobe of the lung which may even cross the middle line. In one case, still under observation, the stomach resonance passed into and was almost part of a tympanitic lung resonance, giving the superficial impression of an extensive pneumothorax. This tympanitic percussion frequently leads to a mistaken diagnosis of pneumothorax. In place of absent breath sounds, we fairly often have tubular breathing, bronchophony, and whispering pectoriloquy, and these signs,

in association with the pyrexia, may lead to a mistaken diagnosis of pneumonia—the so called "traumatic" pneumonia of the early stages of the war. It has been well said that, in the first two or three days, we have urgent symptoms and few physical signs, and that afterward there are few symptoms but well marked signs.

The symptoms of septic hemothorax (pyohemothorax) are much more pronounced. The patient is obviously ill, there is a higher temperature of the swinging type; a rapid pulse; increasing dyspnea; a dry, furred tongue, particularly in the streptococcal cases, and usually considerable local pain and tenderness over the affected side. The physical signs are the same as in sterile cases except that friction is usually more pronounced and may be pleuropericardial as well as pleural.

Fig. 3.—Radiograph from case of hemopneumothorax after recovery. Patient wounded in Gallipoli in right chest by shrapnel bullet. Staff surgeon reported hemothorax at base and pneumothorax in the upper part of right chest. The x rays showed well marked opacity of right chest with no movement of diaphragm on right side. Clinically there was immobility, dullness, and retraction. (Radiograph by Mr. Shenton.)

Value of exploration. Rose Bradford believes that patients with hemothorax, which does not definitely improve by the fourth day after wound, must be regarded with suspicion, as being possibly septic, and that, accordingly, the chest should be explored and a bacteriological examination of the fluid made without delay. The fluid so obtained on exploration may, in some cases, show a yellowish deposit of pus on standing, below the supernatant blood and serum; but, on the other hand, the fluid, though septic, may have the appearance and rich color of normal blood, with no obvious purulent character, and yet this blood may be found teeming with streptococci. When the anaerobic, gas producing bacilli are present, the fluid obtained on exploration has an extremely offensive, fecal odor. It is important to remember that the clots in the hemothorax may be the only infected portions to begin with, the free fluid becoming infected at a later period. This proved to be the case in about twenty per cent. of Bradford and Elliott's bacillary cases during the first week. In these, the brownish red fluid obtained on the fifth and sixth day was sterile, while a few days later it was full of anaerobes. As a general rule, the larger the hemorrhage into the pleural cavity, the greater is the risk of sepsis.

Double hemothorax is a very rare condition, but has been met with by Bradford and others in lateral transverse wounds; the hemothorax may be sterile on both sides, or both effusions may be septic, or one may be septic and the other sterile.

Prognosis in hemothorax. For some time, it may be months or even years, there may be dyspnea on exertion (e. g., when going upstairs or climbing hills), depending, to a great extent, on the degree of permanent pulmonary collapse which has supervened. A functional or nervous element has been noted in certain instances, the patient for a time being too frightened to breathe naturally. It is possible that the mechanical alteration of the chest contents may, in some instances, temporarily alter the nervous mechanism of respiration.

Immobility and retraction of the affected part of the chest is extremely common and is almost invariably present in large effusions not treated by aspiration; the earlier the aspiration, the less likelihood there is of pulmonary collapse and consequent immobility and retraction. The writer has a case now under his care in which the chest expansion has been reduced by three inches, while marked retraction is indicated by the calliper tracings.

As regards mortality, Bradford and Elliott's 450 cases gave a total death rate for all cases of ten per cent. Of the fatal cases, seventy per cent. were such from sepsis, five per cent. from simple hemorrhage, and twenty per cent. from various complications, such as spinal and abdominal injuries, contralateral pneumonia, etc.

Death from simple hemorrhage did not occur if the patient survived the third day, no doubt owing to the sealing of the wounds by deposition of fibrin. This fact is of extreme importance in regard to transport, for the movement involved in careful removal to the base after the fourth day does not materially increase the risk of danger from further hemorrhage, while, on the other hand, it enormously increases the facilities for appropriate treatment at the base hospital, whether this is aspiration in sterile hemothorax, or rib resection and evacuation in septic cases.

Apart from the immediate risk of the first three days from fatal hemorrhage, the prognosis depends almost entirely on the presence or absence of sepsis. In the aseptic cases the fluid is gradually absorbed, with or without the assistance of aspiration. As regards the septic cases, the prognosis depends upon the celerity with which the diagnosis of infection is

made, and the promptness with which the rib resection and evacuation of the septic pleural contents is carried out.

As regards the treatment of sterile hemothorax, the old safe policy of expectant treatment, or, as it might be called, that of "judicious noninterference," has been to a large extent replaced by more active and effective measures, designed to prevent the occurrence of a greater or less degree of permanent pulmonary collapse. In cases which are not interfered with, the blood is gradually absorbed, but the process may take some months, and, in the case of large effusions, some physical signs of thickened pleura and chest retraction, almost invariably remain. (Fig. 3.) It may be laid down as a safe rule that, in cases treated in properly equipped hospitals, all large blood effusions, with a dullness extending halfway up the scapula, should be aspirated, with a view of preventing pulmonary collapse, and consequent permanent impairment of respiratory activity. It is, however, sometimes a wise proceeding "to play for safety" in the absence of adequate hospital aseptic facilities, and not to aspirate, as the conversion of a sterile into a septic hemothorax would be a calamity.

Methods of aspiration. The most rigid aseptic precautions are necessary, as the blood clot is such an excellent nutritive medium for bacterial growth. A sterile hemothorax should never be incised and drained, as it will almost certainly become infected. The presence of clot sometimes tends to hinder aspiration, and, in order to avoid trouble from blocking of the cannula, the aspirator needle should be introduced well forward in the axilla, and fairly high up, on account of the high dome of the diaphragm. The main portion of the clot accumulates in the paravertebral space behind and in the cul-de-sac of the diaphragm. A convenient site for puncture—whether exploratory or aspiratory—is in the sixth or seventh interspace in the midaxillary line, where the depth from the skin surface to the pleura is from one to one and a half inch. A second paracentesis is rarely necessary, for there is no tendency for a sterile hemothorax to reaccumulate.

If aspiration can be combined with oxygen replacement, so much the better, as the results obtained by this method are wonderfully good. The great advantage of oxygen replacement over ordinary paracentesis thoracis is, that the whole of the fluid may be removed without risk of discomfort to the patient. The introduction of the oxygen removes all pain and tendency to cough. This procedure, however, necessitates familiarity and experience with the apparatus for producing artificial pneumothorax. In most cases, simple aspiration is quite satisfactory when followed up by appropriate breathing exercises. Rose Bradford speaks enthusiastically of the results of oxygen replacement.

As regards the treatment of septic cases, pyohemothorax, the role of the physician is to make the diagnosis as early as possible. If the patient's condition does not improve within the first week, and more particularly if the pain and dyspnea continue and the pyrexia is of a swinging character, it is the medical officer's duty to explore the chest and have the fluid examined bacteriologically. If the blood proves to be infected, the sooner a surgeon is called in to resect a rib and evacuate the septic pleural contents the better.

b. Pyothorax. Pyothorax is thus in the large majority of instances a *pyohemothorax*, for uncomplicated empyema, as the result of perforating injuries is comparatively rare. The infection may reach the pleura from the carrying in of septic material
